List of Figures

4.1	Dataflow and control flow in Tycho. Metric sources feed collectors and the metadata subsystem, which populate the buffering layer and metadata cache. The timing engine inspects buffered data to define analysis windows and trigger evaluation. The analysis engine performs attribution for each window and the exporter publishes the resulting metrics. Calibration observes long-term behaviour and feeds auxiliary information back into timing and analysis.	37
4.2	Conceptual relation between physical behaviour (event time) and observations recorded at poll time. Tycho records poll-time timestamps and interprets them as approximations of underlying event-time behaviour in the analysis phase.	38
4.3	Independent sampling schedules for different collectors on a shared time axis. Each collector operates on its own cadence without synchronisation, and samples are later aligned only at the level of analysis windows.	38
4.4	Analysis window W_i defined by two successive analysis trigger times. Samples inside the window contribute directly to reconstruction, while samples outside may still inform background characterisation but are not attributed to W_i	39
4.5	Conceptual comparison between Kepler and Tycho timing. Kepler uses a synchronous polling interval for most domains and reuses slower Redfish readings across multiple intervals; export may occur on a different cadence. Tycho employs independent collectors and defines attribution strictly in terms of analysis windows, with export immediately following each window.	39
4.6	Conceptual view of GPU power as a continuous signal, periodically updated internal NVML values, and Tycho's phase-aware sampling aligned to these updates. No specific update interval or magnitude is implied.	40
4.7	Conceptual mapping ladder from operating-system processes to Kubernetes-level workload identities. Tycho's metadata subsystem maintains these relationships over time to support container-level attribution.	40
5.1	Phase-aware GPU polling timeline	53

*The global climate crisis is one of humanity's greatest challenges in this century.
With this work, I hope to contribute a small part in the direction we urgently need to go.*

Chapter 1

Introduction

XX
 REVISE ENTIRE CHAPTER LATER XXXXXXXXXXXXXXXXXXXXXXX

1.1 Motivation

Energy consumption in data centers continues to rise as demand for compute-intensive and latency-sensitive services increases. Modern cloud platforms host diverse workloads such as machine learning inference, analytics pipelines, and high-density microservices, all of which collectively contribute to a growing global electricity footprint. Container orchestration frameworks amplify these trends by enabling dense consolidation of workloads across shared servers. While this improves resource efficiency, it also introduces abstraction layers that obscure the relationship between workload behaviour and physical energy use.

As interest in sustainable cloud operations intensifies, there is increasing demand for precise, workload-level energy visibility. Fine-grained and reproducible energy measurements are essential for research domains such as performance engineering, scheduling, autoscaling, and the design of energy-aware systems. Existing tools provide valuable approximations but prioritise portability and low operational overhead, and therefore do not target the upper bounds of measurement fidelity. Research environments, by contrast, require methodologies that prioritise accuracy, control, and verifiability over deployability.

This thesis is motivated by the need for an accuracy-focused measurement approach that supports rigorous experimental work on containerised systems. Rather than proposing new optimisation mechanisms, this work concentrates on establishing a reliable methodological foundation for observing and analysing workload-induced energy consumption in controlled settings.

1.2 Problem Context

Modern multi-tenant servers host many short-lived and highly dynamic workloads that execute concurrently and compete for shared hardware resources. On such systems, the aggregate power draw represents the combined activity of numerous interacting subsystems, while the contributions of individual workloads remain deeply entangled. Containerisation further complicates this picture: processes belong to containers, containers belong to pods, and pods may change state rapidly under

orchestration. These abstractions improve system management but obscure how computational activity translates into power consumption.

At the same time, servers expose a heterogeneous collection of telemetry sources. Each source reflects different aspects of hardware behaviour, updates at its own cadence, and provides only a partial view of system activity. Because workload state changes and telemetry updates occur independently, they do not naturally align in time. The resulting temporal misalignment limits the reliability of workload-level energy attribution and leads to uncertainty in short-duration or phase-sensitive analyses.

Kubernetes introduces additional challenges. Workloads may start and terminate within milliseconds, metadata may appear with delays, and lifecycle events may interleave in complex ways. Existing tools often rely on coarse sampling windows or heuristic models that mask these inconsistencies. While sufficient for operational monitoring, such abstractions constrain the achievable accuracy in research settings. An accuracy-oriented approach requires explicit treatment of timing, metadata consistency, and correlation across heterogeneous measurement sources.

1.3 Position Within Previous Research

This thesis builds upon two earlier stages of work. The implementation-focused VT1 project developed an initial measurement pipeline and explored practical aspects of collecting hardware and system-level metrics in a Kubernetes environment. The subsequent VT2 project examined the state of the art in server-level energy measurement, validated the behaviour of commonly used telemetry sources, and identified methodological and technical limitations in existing tools such as Kepler. Both works are included in the appendix as supporting material.

The present thesis integrates these earlier insights but does not repeat them. Instead, it synthesises the essential findings from VT2 in a condensed form ([Chapter 2](#)), and introduces the conceptual foundations required to reason about accurate energy attribution ([Chapter 3](#)). These chapters provide the background necessary to understand the accuracy-focused architecture developed later in this thesis.

1.4 Problem Statement

Accurately determining how much energy individual workloads consume in a Kubernetes cluster remains a challenging open problem. Clusters host many short-lived and overlapping workloads whose behaviour evolves rapidly, while server-level power telemetry is exposed through heterogeneous interfaces that update asynchronously and lack consistent timestamps. These timing mismatches, combined with the abstraction layers introduced by container orchestration, obscure the relationship between workload activity and physical energy use. Existing approaches provide high-level estimates but cannot deliver the temporal alignment, attribution fidelity, or reproducibility required for rigorous experimental analysis. This thesis therefore addresses the problem of designing a measurement methodology and prototype system capable of producing time-aligned, workload-level energy attribution with sufficient accuracy for research environments.

1.5 Goals of This Thesis

The overarching goal of this thesis is to develop an accuracy-focused approach for measuring energy consumption in Kubernetes-based environments. To achieve this, the work pursues four concrete objectives:

- **Methodological objective:** Define a measurement methodology that aligns heterogeneous telemetry sources with dynamic workload behaviour under a unified temporal model suitable for controlled research settings.
- **Architectural objective:** Design an accuracy-first system architecture that explicitly handles timing, metadata consistency, and correlation across diverse metrics without relying on heuristic abstractions.
- **Prototype objective:** Implement a research prototype that realises this architecture on commodity server hardware and integrates workload metadata, timing information, and server-wide telemetry into a coherent measurement pipeline.
- **Foundational objective for future work:** Establish the methodological and architectural basis for subsequent validation studies that will evaluate measurement fidelity and explore trade-offs between accuracy, overhead, and operational constraints.

1.6 Research Questions

1. How reliably can an accuracy-focused measurement approach capture and represent workload-induced variations in energy consumption within dynamic, multi-tenant Kubernetes environments?
2. To what extent does a unified timing and attribution methodology improve the consistency and interpretability of workload-level energy measurements compared to existing estimation-oriented approaches?
3. In which contexts does high-fidelity energy measurement provide meaningful benefits for research and experimental analysis, and what trade-offs arise between accuracy, overhead, and operational constraints?

1.7 Contributions

This thesis makes several conceptual and methodological contributions to the study of energy measurement in container-orchestrated environments. First, it introduces an accuracy-focused measurement approach that prioritizes temporal consistency, reproducibility, and the faithful representation of workload behaviour. The work defines a methodology for unifying heterogeneous sources of server telemetry under a shared timing model, enabling coherent interpretation of workload activity and system-level energy use.

A second contribution is the development of a prototype system that operationalizes this methodology and provides a concrete platform for exploring the limits of

high-fidelity energy measurement in Kubernetes-based environments. The prototype integrates workload metadata, timing information, and server-wide telemetry into a coherent measurement pipeline designed for research and controlled experimentation.

Third, the thesis establishes a foundation for reliable workload-level attribution by describing a structured process for correlating dynamic workload behaviour with system energy consumption. This provides a basis for analysing short-lived workload phases, transient resource usage patterns, and other phenomena that require fine-grained temporal alignment.

Finally, the work prepares the methodological groundwork for subsequent validation studies by outlining experimental procedures, calibration strategies, and evaluation principles suited to accuracy-oriented measurement. Together, these contributions advance the methodological state of the art and offer a practical reference point for future research on energy transparency in modern cloud infrastructures.

1.8 Scope and Boundaries

This thesis focuses on high-level principles and methods for energy measurement in multi-tenant server environments. The primary scope includes conceptual design, prototype development, and preparation of the methodological foundation for subsequent evaluation work. The emphasis is on accuracy, reproducibility, and consistency rather than operational deployability or production-grade integration.

Several areas remain outside the scope of this work. The thesis does not propose scheduling policies, predictive models, or system-level optimisation mechanisms. It does not modify Kubernetes or introduce changes to cloud operators' workflows. The prototype developed in this thesis is intended for controlled research environments and does not aim to provide a turnkey solution for general-purpose use. The work assumes access to a server environment where low-level telemetry and measurement interfaces are accessible under suitable conditions.

1.9 Origin of the Name “Tycho”

The prototype developed in this thesis is named *Tycho*, a reference to the astronomer Tycho Brahe. Brahe is known for producing exceptionally precise astronomical measurements, which later enabled Johannes Kepler to formulate the laws of planetary motion. The naming reflects a similar relationship: while the upstream *Kepler* project focuses on modelling and estimation, this thesis explores the upper bounds of measurement accuracy. Tycho thus signals both continuity with prior work and a shift toward an accuracy-first design philosophy.

1.10 Methodological Approach

1.11 Thesis Structure

Chapter 2

Background and Related Research

This chapter summarises the current state of research and industrial knowledge on server-level energy measurement. Its focus is limited to what the literature reports about available telemetry sources, measurement techniques, and existing attribution tools. The discussion is descriptive rather than conceptual: it does not introduce attribution principles, methodological reasoning, or design considerations, which are addressed in [Chapter 3](#). Extended background material is available in [Appendix A](#) and the present chapter integrates only those findings that are directly relevant for understanding the research landscape.

2.1 Energy Measurement in Modern Server Systems

The energy consumption of modern servers arises from a heterogeneous set of subsystems, including CPUs, GPUs, memory, storage devices, network interfaces, and platform management components. Prior research highlights that these subsystems expose highly unequal visibility into their power behaviour, since measurement capabilities, granularity, and accuracy differ significantly across hardware generations and vendors [2, 3]. Some domains provide direct telemetry, while others can only be approximated through software-derived activity metrics. As a result, no single interface offers complete or temporally consistent power information, and most studies rely on a single source or combine multiple sources to approximate system-level consumption. This fragmented measurement landscape forms the basis for much of the existing work on power modelling, validation, and multi-source energy estimation in server environments.

2.1.1 Energy Attribution in Multi-Tenant Environments

Several studies identify containerised and multi-tenant systems as challenging environments for energy attribution. Containers share the host kernel and rely on common processor, memory, storage, and network subsystems, which removes the isolation boundaries present in virtual machines and prevents direct measurement of per-container power. Research reports that workloads running concurrently on the same node create interference effects across hardware domains, leading to utilisation patterns that correlate only loosely with actual energy consumption [2]. Modern orchestration platforms further increase attribution difficulty through highly dynamic execution behaviour: containers are created, destroyed, and rescheduled at high frequency, often numbering in the thousands on large clusters. These rapid lifecycle changes produce volatile metadata and short-lived resource traces that are difficult

to align with node-level telemetry. Collectively, the literature treats container-level energy attribution as an estimation problem constrained by incomplete observability, heterogeneous measurement quality, and continuous runtime churn.

2.1.2 Telemetry Layers in Contemporary Architectures

Modern servers expose power and activity information through two largely independent telemetry layers. The first consists of in-band mechanisms that are visible to the operating system, including on-die energy counters, GPU management interfaces, and kernel-level resource statistics. These interfaces typically offer higher sampling rates and finer granularity, but their accuracy and coverage vary across hardware generations and vendors. Prior work notes that in-band telemetry often represents estimated rather than directly measured power and that several domains, such as network and storage devices, expose only partial or indirect information.

The second layer is out-of-band telemetry provided by baseboard management controllers through interfaces such as IPMI or Redfish. These systems aggregate sensor readings independently of the host and report stable, whole-system power values at coarse temporal resolution. Empirical studies show that out-of-band telemetry provides useful system-level accuracy, although update intervals and measurement precision differ substantially between vendors [4]. Compared with instrument-based measurements, which remain the benchmark for high-fidelity evaluation but are impractical at scale, both in-band and out-of-band methods represent trade-offs between granularity, availability, and measurement reliability.

Combined, these layers form a heterogeneous telemetry landscape in which sampling rates, accuracy, and domain coverage differ significantly, motivating the use of multi-source measurement approaches in research.

2.1.3 Challenges for Container-Level Measurement

Existing research identifies several factors that complicate accurate energy measurement for containerised workloads. Large-scale trace analyses show that cloud environments exhibit substantial churn, with many tasks being short-lived and resource demands changing rapidly over time [5]. Such dynamism limits the observability of fine-grained resource usage and makes it difficult to capture short execution intervals with sufficient temporal resolution.

Monitoring studies further report inconsistencies across the different layers that expose resource information for containers. In multi-cloud settings, observability often depends on heterogeneous monitoring stacks, leading to fragmented visibility and non-uniform coverage of system activity [6]. Even within a single host, performance counters obtained from container-level interfaces may diverge from system-level measurements. Empirical evaluations demonstrate that container-level CPU and I/O counters can underestimate actual activity by a non-negligible margin, and that co-located workloads introduce contention effects that distort these metrics [7].

These findings indicate that container-level measurement operates under conditions of rapid workload turnover, heterogeneous monitoring behaviour, and imperfect resource visibility. As a consequence, the literature treats container energy attribution as a problem constrained by incomplete and potentially biased measurement signals rather than as a directly measurable quantity.

2.2 Hardware and Software Telemetry Sources

This section outlines the primary telemetry sources used to observe power and resource behaviour in modern server systems. It summarises established research on external measurement devices, firmware-level interfaces, on-die energy counters, accelerator telemetry, and kernel-exposed resource metrics. The emphasis is on reporting the properties and empirical characteristics documented in prior work, without interpreting these signals conceptually or analysing their temporal behaviour, which are addressed in later sections. A comprehensive technical discussion is provided in [Appendix A, Chapter 2](#); the present section extracts only the findings relevant for understanding the measurement landscape.

2.2.1 Direct Hardware Measurement

Direct physical instrumentation remains the most accurate method for measuring server power consumption. External power meters or inline shunt-based devices can capture node-level energy usage with high fidelity, and research frequently uses such instrumentation as a ground truth for validating software-reported power values. Studies employing dedicated measurement setups, such as custom DIMM-level sensing boards, demonstrate that high-frequency sampling and component-level granularity are technically feasible but require bespoke hardware and non-trivial integration effort [8]. Lin et al. classify these approaches as offering very high data credibility but only coarse spatial granularity and limited scalability in operational environments [2].

Recent work on specialised sensors, such as the PowerSensor3 platform[9] for high-rate voltage and current monitoring of GPUs and other accelerators, illustrates ongoing interest in hardware-centric power measurement. However, these systems share the same fundamental drawback: deployment across production servers is complex, costly, and incompatible with large-scale or multi-tenant settings. As a consequence, direct instrumentation is predominantly used in controlled experiments or for validation of other telemetry sources, rather than as a primary measurement mechanism in real-world server infrastructures.

2.2.2 Legacy Telemetry Interfaces (ACPI, IPMI)

Early power-related telemetry on server platforms was primarily exposed through ACPI and IPMI. ACPI provides a standardised interface for configuring and controlling hardware power states, but it does not offer real-time energy or power readings. The interface exposes only abstract performance and idle states defined by the firmware [10], and these states do not include the instantaneous power information required for empirical energy measurement. Consequently, ACPI has seen little use in modern power estimation research.

IPMI, accessed through the baseboard management controller, represents an older class of out-of-band telemetry that predates Redfish. Although widely supported across server hardware, IPMI power values are known to be coarse, slowly refreshed, and often inaccurate when compared with external instrumentation. Empirical studies report multi-second averaging windows, substantial quantisation effects, and unreliable idle power readings [11, 12]. These limitations, together with the availability of more precise alternatives, have led IPMI to be largely superseded by Redfish on contemporary server platforms.

2.2.3 Redfish Power Telemetry

Redfish is the modern out-of-band management interface available on contemporary server platforms and is designed as the successor to IPMI. It exposes system-level telemetry through a RESTful API implemented on the baseboard management controller (BMC), providing access to whole-node power readings derived from on-board sensors. Prior work consistently shows that Redfish delivers higher precision than IPMI, with lower quantisation artefacts and more stable readings across power ranges [4]. In controlled experiments, Redfish achieved a mean absolute percentage error of roughly three percent when compared to a high-accuracy power analyser, outperforming IPMI in all evaluated power intervals.

A key limitation of Redfish is its temporal granularity. Empirical studies report that power values exhibit non-negligible staleness, with refresh delays of approximately 200 ms [4]. This latency restricts the ability of Redfish to capture short bursts of activity or rapid fluctuations in dynamic workloads. Accuracy and responsiveness also vary across vendors, reflecting differences in embedded sensors, BMC firmware, and management controller architectures.

The interface is widely deployed in real-world infrastructure. Modern enterprise servers from Dell, HPE, Lenovo, Cisco, and Supermicro routinely expose power telemetry via Redfish as part of their standard BMC firmware [13]. Out-of-band monitoring studies further highlight that Redfish avoids the overheads and failure modes associated with in-band agents [14]. In practice, Redfish implementations tend to provide stable low-frequency updates suitable for coarse-grained power reporting.

Preliminary measurements conducted for this thesis also observed irregular update intervals on the evaluated hardware, occasionally extending into the multi-second range. While this behaviour is specific to a single system and not generalisable, it reinforces the literature's position that Redfish telemetry exhibits meaningful vendor-dependent variability and remains unsuitable for fine-grained temporal correlation.

Overall, Redfish provides accessible, reliable whole-node power telemetry at coarse temporal resolutions, making it valuable for long-interval monitoring and for validating other measurement sources, but inappropriate for attributing energy consumption to short-lived or rapidly fluctuating containerised workloads.

2.2.4 RAPL Power Domains

Running Average Power Limit (RAPL) provides hardware-backed energy counters for several internal power domains of a processor package. Originally introduced by Intel and later adopted in a compatible form by AMD, RAPL exposes energy measurements via model-specific registers that can be accessed directly or through higher-level interfaces such as the Linux `powercap` framework or the `perf-events` subsystem [15, 16]. Raffin et al. provide a detailed comparison of these access mechanisms, noting that MSR, powercap, perf-events, and eBPF differ mainly in convenience, required privileges, and robustness; all can retrieve equivalent RAPL readings when implemented correctly [16]. They recommend accessing RAPL via the `powercap` interface, which is easiest to implement reliably and suffers from no overhead penalties when compared with more low-level methods.

Intel platforms typically expose several well-established RAPL domains, including the processor package, the core subsystem, and (on many server architectures) a DRAM domain [17]. These domains have been validated extensively against external measurement equipment. Studies report that the combination of package and DRAM energy tracks CPU-and-memory power with good accuracy from Haswell onwards, which has led to RAPL becoming the primary fine-grained energy source in server-oriented research [8, 18–20]. More recent work on hybrid architectures such as Alder Lake confirms that RAPL continues to correlate well with external measurements under load, while precision decreases somewhat in low-power regimes [21]. Across these studies, RAPL is generally regarded as sufficiently accurate for scientific analysis when its domain boundaries and update characteristics are considered [16].

AMD implements a RAPL-compatible interface with a similar programming model but a reduced set of domains. Zen 1 through Zen 4 processors expose package and core domains only, without a dedicated DRAM domain [16, 22]. Schöne et al. show that, as a consequence, memory-related energy may not be represented explicitly in AMD’s RAPL output, leading to a smaller portion of total system energy being observable through the package domain alone [22]. This limitation primarily concerns domain completeness rather than measurement correctness: for compute-intensive workloads, package-domain values behave consistently, but workloads with significant memory activity exhibit a larger gap relative to whole-system measurements because DRAM energy is not separately reported. Raffin et al. further note that, on the evaluated Zen-based server, different kernel interfaces initially exposed inconsistent domain sets; this was later corrected upstream, illustrating that AMD support is evolving and still maturing within the Linux ecosystem [16].

Technical considerations also apply to both Intel and AMD platforms. RAPL counters have finite width and wrap after sufficiently large energy accumulation, requiring consumers to implement overflow correction [16, 23]. The counters do not include timestamps, and empirical work shows that actual update intervals may deviate from nominal values, complicating precise temporal correlation with other telemetry [18, 24]. On some Intel platforms, security hardening measures such as energy filtering reduce temporal granularity for certain domains to mitigate side-channel risks [21, 25, 26]. In virtualised environments, RAPL access may be trapped by the hypervisor, increasing latency and introducing small deviations from bare-metal behaviour [24].

In summary, RAPL provides a widely used and comparatively fine-grained source of processor-side energy telemetry. Intel platforms typically offer multiple validated domains, including DRAM, enabling a broader view of CPU-and-memory energy. AMD platforms expose fewer domains and therefore provide a more limited perspective on total system power, particularly for memory-intensive workloads. These differences in domain coverage, measurement scope, and software integration need to be taken into account when using RAPL as a basis for energy analysis.

2.2.5 GPU Telemetry

Unlike CPUs, where power and utilization telemetry is supported through standardised interfaces, GPU energy visibility relies primarily on vendor-specific mechanisms. For NVIDIA devices, two interfaces dominate this landscape: the *NVIDIA Management Library* (NVML), which has become the industry standard, and the *Data*

Center GPU Manager (DCGM), a less widely used management layer that also exposes telemetry.

2.2.5.1 NVML

NVML is NVIDIA’s primary interface for device-level monitoring and underpins tools such as `nvidia-smi`. It provides access to power, energy (on selected data-center GPUs), GPU utilization, memory usage, clock frequencies, thermal state, and various health and throttle indicators. Among these, power and utilization are most relevant for energy analysis.

NVML power values represent board-level estimates derived from on-device sensing circuits and are shaped by internal averaging and architecture-dependent update behaviour. Recent empirical studies across modern devices show that NVML produces fresh samples only intermittently and applies smoothing that reduces the visibility of short-lived power changes, while steady-state power levels remain comparatively accurate [27]. On the Grace-Hopper GH200, these effects are pronounced: NVML reflects a coarse internal averaging interval and therefore underrepresents short kernels and transient peaks relative to higher-frequency system interfaces [28]. These findings indicate that NVML captures long-term power behaviour reliably but inherently limits fine-grained visibility. Despite these constraints, existing studies consistently find that NVML provides reasonably accurate steady-state power estimates on modern data-center GPUs and currently represents the most reliable and widely supported mechanism for obtaining GPU power telemetry in practical systems [28].

GPU utilization provides contextual information about device activity. It reports the proportion of time during which the GPU is executing any workload rather than the fraction of computational capacity in use, making it a coarse activity indicator rather than a detailed performance metric [29].

2.2.5.2 DCGM

DCGM is NVIDIA’s management and observability framework designed for data-center deployments. It aggregates telemetry, performs health monitoring, exposes thermal and throttle state, and provides detailed visibility in environments that employ Multi-Instance GPU (MIG) partitioning. However, DCGM’s power and utilization metrics are derived from the same underlying measurement sources as NVML. In practice, DCGM is far less commonly used for energy analysis because it does not provide higher-fidelity power telemetry; instead, it applies additional aggregation and is typically deployed with coarse sampling intervals, especially when used through exporters in cluster monitoring systems. DCGM therefore represents an alternative access path to the same measurements rather than a distinct source of energy-related information.

DCGM is considerably less common in both research and operational practice, with most GPU monitoring systems relying primarily on NVML while DCGM appears only occasionally in cluster-level deployments [29].

2.2.5.3 Summary

NVML and DCGM jointly define the available mechanisms for GPU telemetry in cloud environments. NVML is the dominant and broadly supported interface for power and utilization measurement, while DCGM extends it with operational metadata and management integration. Current studies consistently show that both interfaces expose averaged, device-level power estimates that capture long-term behaviour but are inherently limited in their ability to represent short-duration activity or fine-grained workload structure. These characteristics form the scientific foundation for later discussions of temporal behaviour and measurement methodology.

2.2.6 Software-Exposed Resource Metrics

In addition to hardware telemetry, Linux and Kubernetes expose a wide range of software-level resource metrics that describe system and workload activity. These metrics do not measure power directly but provide essential behavioural context that complements RAPL, Redfish, and GPU telemetry.

2.2.6.1 CPU and Memory Activity Metrics

Linux provides several complementary mechanisms for tracking CPU and memory usage. Global counters such as `/proc/stat` record cumulative CPU time since boot, while per-task statistics in `/proc/<pid>` expose user-mode and kernel-mode execution time with high granularity [30]. Control groups (`cgroups`) provide container-level CPU and memory accounting and form the primary basis for utilisation metrics inside Kubernetes [31, 32]. Higher-level tools such as `cAdvisor` and `metrics-server` aggregate this information via `Kubelet`, but at significantly lower update rates.

Event-driven approaches provide substantially finer resolution. eBPF allows dynamic attachment to kernel events such as context switches, scheduling decisions, and I/O operations, enabling near-real-time capture of per-task CPU activity with low overhead [33, 34]. Hardware performance counters accessed through `perf` offer insight into instruction counts, cycles, cache behaviour, and stalls [35]. These sources provide detailed behavioural information but still represent utilisation rather than energy.

2.2.6.2 Storage Activity Metrics

Storage subsystems do not expose real-time power telemetry, yet Linux provides a rich set of activity indicators. Per-process statistics in `/proc/<pid>/io` track bytes read and written, while cgroup I/O controllers report aggregated container-level metrics. Subsystem-specific tools such as `smartctl` and `nvme-cli` reveal additional device characteristics, queue behaviour, and state transitions [36, 37].

In the absence of hardware power sensors, multiple works propose workload-dependent energy models for storage devices [38–40]. These models can yield accurate estimates when calibrated for a specific device but do not generalise across heterogeneous hardware due to differences in flash controllers, firmware, and internal data paths.

2.2.6.3 Network and PCIe Device Metrics

Network interfaces provide byte and packet counters via `/proc/net/dev`, but expose no dedicated power telemetry. Research models for NIC energy consumption exist [41–43], yet all rely on device-specific idle and active power characteristics that are not available at runtime. Similarly, PCIe devices support abstract power states as defined by the PCIe specification [44], but these states do not reflect instantaneous power usage and thus offer only coarse activity signals.

2.2.6.4 Secondary System Components

Components such as fans, motherboard logic, and power delivery subsystems rarely expose fine-grained telemetry. Although some BMC implementations report coarse sensor values, these readings are inconsistent across platforms and generally unsuitable for high-resolution analysis. Consequently, research commonly treats these subsystems as part of the residual power that scales with the activity of primary components [42].

2.2.6.5 Model-Based Estimation Approaches

Because software-visible metrics capture detailed workload behaviour, many works propose inferring energy consumption from utilisation using regression or stochastic models [45–48]. While these models can be effective when fitted to a specific hardware platform, their accuracy depends heavily on device-specific parameters, making them unsuitable as a general mechanism for heterogeneous server environments. Machine-learning-based estimators share the same limitation: high accuracy when trained for a fixed configuration, poor portability without extensive retraining.

2.2.6.6 Summary

Software-exposed metrics provide high-resolution visibility into CPU, memory, I/O, and network activity. They are indispensable for correlating workload behaviour with hardware power signals, especially for components that lack native telemetry. Model-based estimation remains possible but inherently platform-specific, and therefore unsuitable as a universal foundation for fine-grained attribution in heterogeneous environments.

2.3 Temporal Behaviour of Telemetry Sources

A comprehensive treatment of temporal characteristics can be found in [Appendix A](#), [Chapter 2](#), but the present section focuses on the empirical, source-specific behaviours that constrain fine-grained power and energy estimation on real systems. Modern server platforms expose a heterogeneous set of telemetry interfaces, and their timing properties vary substantially: some update at fixed intervals, others employ internal averaging or smoothing, several expose counters without timestamps, and many lack guarantees on refresh regularity. These behaviours shape the effective temporal resolution with which workload-induced power changes can be observed.

The purpose of this section is not to develop a conceptual theory of sampling or to explain why timing matters for attribution (both are deferred to [Chapter 3](#)), nor to introduce Tycho’s timing engine ([Chapter 4](#)). Rather, it establishes the empirical constraints imposed by the telemetry sources themselves. These include sensor refresh

intervals, stability of consecutive updates, delays between physical behaviour and reported values, the presence or absence of timestamps, and the distinction between instantaneous versus internally averaged measurements.

The subsections that follow describe these temporal properties for each telemetry source individually and summarise the practical limits they impose on high-resolution energy analysis.

2.3.1 RAPL Update Intervals and Sampling Stability

RAPL exposes energy *counters* rather than instantaneous power values. These counters accumulate energy since boot and can be read at arbitrarily high frequency, but their usefulness is determined entirely by how often the internal measurement logic refreshes them, a timing behaviour that is undocumented and domain-dependent.

Domain-specific internal update rates Intel specifies the RAPL time unit as 0.976 ms for the slowest-updating domains, while others, notably the PP0 (core) domain, may refresh significantly faster [21]. In practice, however, these theoretical limits do not translate into usable temporal resolution because RAPL provides no timestamps: the moment of counter refresh is unknown to the reader. At sub-millisecond sampling rates, the lack of timestamps combined with irregular refresh behaviour introduces substantial relative error, since differences between consecutive reads may reflect counter staleness rather than actual power dynamics [23].

Noise introduced by security-driven filtering To mitigate power-side channels such as Platypus, Intel optionally introduces randomised noise through the ENERGY_FILTERING_ENABLE mechanism [26]. This filtering increases the effective minimum granularity from roughly 1 ms to approximately 8 ms for the PP0 domain [21]. While average energy over longer intervals remains accurate, instantaneous increments become less reliable at very short timescales.

Practical sampling limits Despite the nominal sub-millisecond timing, empirical work consistently shows that high-frequency polling offers no practical benefit. Multiple studies report that sampling faster than the internal update period only produces repeated counter values and amplifies read noise [23]. Jay et al. demonstrate that at polling rates slower than 50 Hz, the relative error falls below 0.5% [24]. Consequently, typical measurement practice (and the limits adopted in this thesis) treats RAPL as reliable only at tens-of-milliseconds resolution, not at the theoretical millisecond scale suggested by its nominal time unit.

Summary Although RAPL counters can be read extremely quickly, the effective temporal resolution is constrained by undocumented refresh intervals, absence of timestamps, optional security filtering, and substantial measurement noise at high polling rates. For practical purposes, sampling at approximately 20–50 ms intervals yields the most stable and accurate results, while sub-millisecond polling is inadvisable due to high relative error and counter staleness.

2.3.2 GPU Update Intervals and Sampling Freshness

GPU power telemetry is exposed primarily through NVML, with DCGM providing an alternative access path that builds on the same underlying measurement

source. Unlike CPU-side interfaces integrated into the processor package, GPU power monitoring is performed entirely by the device itself: internal sensing circuits and firmware determine how often new values are produced, how they are averaged, and when they are published to software. As a result, refresh behaviour varies substantially across architectures, and the temporal properties of the reported values depend on device-internal update cycles rather than the rate at which the host system issues queries, which limits the achievable resolution of any external sampling strategy.

Internal update cycles and sampling freshness Empirical studies consistently show that NVML publishes new power values only intermittently, even when queried at high frequency. Yang et al. report sampling availability as low as roughly twenty–twenty-five percent across more than seventy modern data-center GPUs, meaning that the majority of polls return previously published values rather than fresh measurements [27].

Typical internal update periods fall on the order of tens to several hundreds of milliseconds, with architectural variation between GPU generations. Hernandez et al. report that newer architectures apply more aggressive smoothing and exhibit longer gaps between updates, reflecting slower publication cadence at the firmware level [28]. Overall, empirical evaluations show that NVML’s internal update interval may lie on the order of hundreds of milliseconds and that repeated queries do not guarantee the retrieval of a new sample at every call [27]. NVML power readings do not represent instantaneous electrical measurements; they reflect firmware-level integration and smoothing over a device-internal averaging window, the duration of which varies by GPU generation and is not publicly documented..

Reaction delay to workload-induced power changes A related characteristic is NVML’s reaction delay: when GPU power changes due to workload activity, the corresponding update becomes visible only after a lag. Multiple studies document delays in the range of approximately one to three hundred milliseconds before a new NVML value reflects the underlying power transition [27]. This delay is distinct from averaging effects and arises from deferred publication of internally accumulated measurements. On some recent architectures, the delay can be longer due to device-level smoothing layers that defer updates until sufficient internal samples have been collected [28].

Update regularity and jitter NVML update cycles are not perfectly periodic. Even when a nominal internal cadence is observable, individual publish times exhibit modest jitter, and occasional missed or skipped updates can result in sequences of identical values. These effects are pronounced on certain consumer-class devices and in configurations that partition the GPU, such as MIG, although they are also present to a lesser degree on data-center accelerators [27]. Such irregularity introduces uncertainty regarding the true measurement time of any retrieved value, especially in the sub-second range.

DCGM sampling behaviour DCGM relies on the same underlying measurement path as NVML and therefore inherits NVML’s internal update characteristics. In practice, DCGM is commonly accessed through its exporter, which introduces an additional periodic sampling stage (typically around one second) resulting in markedly

coarser temporal behaviour than NVML’s native cadence. As a result, DCGM-based power telemetry rarely offers sub-second resolution in operational environments [29].

GPU utilization update cycles NVML’s GPU utilization metric follows its own internal update cadence, separate from power. It is typically refreshed more frequently (on the order of tens of milliseconds) although the exact timing remains undocumented. While this metric does not track computational efficiency, its shorter update interval provides a comparatively more responsive indicator of device activity [29].

2.3.3 Redfish Sensor Refresh Intervals and Irregularity

Redfish exposes power telemetry through the baseboard management controller (BMC) and therefore inherits the temporal behaviour of its embedded sensing hardware and firmware. In contrast to on-chip interfaces such as RAPL or NVML, Redfish is designed for management-plane observability rather than high-frequency monitoring. Prior studies consistently report that Redfish refreshes whole-node power values at coarse intervals, typically ranging from several hundred milliseconds to multiple seconds, with the exact cadence depending on vendor, BMC firmware, and underlying sensor design [4, 14]. The Redfish standard does not define a minimum update frequency, and available documentation provides little insight into internal sampling or averaging strategies.

Measurement semantics of Redfish power values Redfish does not expose instantaneous electrical measurements. Instead, the reported values originate from on-board monitoring chips connected to shunt-based sensors and are subsequently processed inside the BMC. Vendor documentation indicates that these sensors inherently integrate power over tens to hundreds of milliseconds, and that additional firmware-level smoothing may be applied before values are published through the Redfish API [14]. Empirical evaluations support this interpretation: Wang et al. show that Redfish exhibits reaction delays of roughly two hundred milliseconds and displays particularly stable behaviour under steady loads, consistent with block-averaged rather than instantaneous sampling [4]. Because neither the sensor integration window nor any BMC filtering policies are defined in the standard, the temporal semantics of published values remain implementation-dependent.

Redfish power readings include a timestamp field, but this value reflects the BMC’s observation time rather than the sampling instant of the physical power sensor. In many implementations, timestamps are rounded to seconds, which limits their utility for reconstructing sub-second dynamics and prevents reliable inference of the underlying sampling moment.

Beyond published work, empirical observations from the system used in this thesis reveal that Redfish update intervals may exhibit substantial variability. While nominal refresh periods appear regular over longer windows, individual samples occasionally show multi-second gaps, repeated values, or irregular spacing. Such behaviour is consistent with a telemetry source operating on management-plane scheduling and BMC workload constraints rather than real-time guarantees. These observations do not generalise across vendors but illustrate the degree of temporal uncertainty that can occur in practice.

Overall, Redfish provides a widely supported mechanism for obtaining whole-system power readings and is well suited for coarse-grained monitoring or validation of other telemetry sources. Its coarse refresh intervals, lack of sensor-level timestamps, and implementation-dependent irregularities, however, make it unsuitable for analysing short-duration phenomena or for use as a primary source in high-resolution energy attribution.

2.3.4 Timing of Software-Exposed Metrics

Software-exposed resource metrics differ fundamentally from hardware-integrated telemetry sources: rather than publishing sampled power or energy values at device-defined intervals, the Linux kernel exposes cumulative counters whose temporal behaviour is almost entirely determined by when they are read. These interfaces therefore provide quasi-continuous visibility into system activity, but without intrinsic update cycles or timestamps that would define the sampling moment of the underlying measurement.

Cumulative counters in `/proc` and `cgroups` Kernel interfaces such as `/proc/stat`, per-task entries under `/proc/<pid>`, and the CPU accounting files in `cgroups` expose resource usage as monotonically increasing counters. These values are updated by the kernel during scheduler events, timer interrupts, and context-switch accounting, rather than at fixed intervals. As a consequence, their effective temporal resolution is determined entirely by the user's polling cadence: reading them more frequently produces more detailed deltas, but the kernel does not provide any guarantee about when a counter was last updated. None of these counters include timestamps, and their update timing may vary across systems due to tickless operation, kernel configuration, and workload characteristics.

Disk and network I/O statistics I/O-related counters follow the same principle. Entries such as `/proc/<pid>/io`, cgroup I/O files, and interface statistics in `/proc/net/dev` are incremented as part of the corresponding driver paths when I/O operations occur. They do not refresh periodically and therefore exhibit update patterns that mirror workload activity rather than a regular cadence. Temporal interpretation again depends entirely on the polling rate of the monitoring system.

eBPF-based event timing In contrast to cumulative counters, eBPF enables event-driven monitoring with explicit timestamps. Kernel probes attached to scheduler events, I/O paths, or tracepoints can record event times with high precision using the kernel's monotonic clock. As a result, eBPF metrics provide effectively instantaneous temporal resolution and are limited only by the overhead of probe execution and user-space consumption of BPF maps. No internal refresh cycle exists; events are timestamped at the moment they occur.

Performance counters and `perf`-based monitoring Hardware performance monitoring counters (PMCs), accessed via `perf_event_open`, advance continuously within the processor. They do not follow a publish interval, and their timing semantics are defined solely by the instant at which user space reads the counter. This provides fine-grained and low-latency access to execution metrics such as cycles and retired instructions, with overhead rising only when polling is performed at very high frequencies.

Overall, software-exposed metrics behave as cumulative or event-driven signals rather than sampled telemetry sources. Their temporal characteristics are dominated by polling strategy and kernel-level event timing, with eBPF representing the only interface that attaches precise timestamps directly to system events.

2.4 Existing Tools and Related Work

Energy observability in containerized environments has attracted increasing attention in recent years, leading to the development of several tools that combine hardware, software, and statistical telemetry to estimate per-workload energy consumption. Despite this diversity, only a small number of tools attempt to attribute energy at container or pod granularity with sufficient detail to inform system-level research. Among these, *Kepler* has emerged as the most widely adopted open-source solution within the cloud-native ecosystem, while *Kubewatt* represents the first focused research effort to critically evaluate and refine Kepler’s attribution methodology. Other frameworks, such as Scaphandre, SmartWatts, or PowerAPI, offer relevant ideas but differ in scope, telemetry assumptions, or operational goals. For this reason, the remainder of this section concentrates primarily on Kepler and Kubewatt, using these two tools to illustrate the architectural and methodological challenges that motivate the research gaps identified at the end of this chapter.

2.4.1 Kepler

2.4.1.1 Architecture and Metric Sources

Kepler[49] is a node-local energy observability agent designed for Kubernetes environments. Its architecture follows a modular dataflow pattern: a set of collectors periodically ingests telemetry from hardware and kernel interfaces, an internal aggregator aligns and normalizes these inputs, and a Prometheus exporter exposes the resulting metrics at container, pod, and node granularity. This structure allows Kepler to integrate heterogeneous telemetry sources while presenting a unified metric interface to external monitoring systems.

Kepler’s collectors obtain process, container, and node telemetry from standard Linux and Kubernetes subsystems. Resource usage statistics are taken from `/proc`, cgroup hierarchies, and Kubernetes metadata, while hardware-level energy data is read from RAPL domains via the `powercap` interface. Optional collectors provide GPU metrics through NVIDIA’s NVML library and platform-level power measurements via Redfish or other BMC interfaces. All inputs are treated as cumulative counters or periodically refreshed state, and their effective resolution is therefore determined by Kepler’s sampling configuration. All metrics are updated at same interval and at the same time (default: 60 seconds for redfish, 3 seconds for all other sources). A central responsibility of the aggregator is to map raw per-process telemetry to containers and pods, using cgroup paths and Kubernetes API metadata. The derived metrics are finally exposed via a Prometheus endpoint, enabling integration into common cloud-native observability stacks.

In contrast to generic system monitoring agents, Kepler’s architecture is tailored specifically to Kubernetes. Its emphasis on container metadata, cgroup-based accounting, and workload-oriented metric aggregation distinguishes it from tools that operate primarily at the host or VM level. At the same time, its reliance on standard

Linux interfaces keeps deployment overhead low, requiring only node-local access to `/proc`, cgroups, and the `powercap` subsystem.

Overall, Kepler’s architectural design reflects a trade-off between flexibility and granularity: while it can ingest diverse telemetry sources and attribute energy at container level, its accuracy is constrained by the timing and resolution of the underlying metrics, as well as the unified sampling cadence chosen for the collectors.

2.4.1.2 Attribution Model

Kepler’s attribution logic follows a two-stage structure. First, node-level energy is decomposed into *idle* and *dynamic* components for each available power domain (package, core, uncore, DRAM, and optionally GPU or platform-level readings). Second, the dynamic portion is distributed across processes and containers according to their observed resource usage, while idle power is assigned using a domain-specific default policy.

Dynamic power is attributed proportionally using ratio-based models. For each domain, Kepler computes the energy delta over the sampling interval and distributes it according to a usage metric selected for that domain. Instructions, cache misses, and CPU time are used as primary signals, with fallbacks when a metric is unavailable. GPU dynamic power is attributed based on GPU compute utilization. Platform-level power, when available, is treated as a residual domain: after subtracting CPU and DRAM power, the remaining portion is shared across workloads using the designated default metric or, if none is configured (which is the case), an equal split.

Idle energy is handled separately. Kepler maintains a rolling estimate of minimum node-level power for each domain and treats these values as idle baselines. In the default configuration, idle energy is divided evenly across all active workloads during the attribution interval. While this behaviour differs from protocol recommendations that scale idle power by container size, Kepler applies a uniform policy across domains to ensure attribution completeness.

Attribution operates at process granularity, with container and pod values obtained by aggregating the processes mapped to each cgroup. This approach allows Kepler to attribute energy to short-lived or multi-process containers while retaining compatibility with Kubernetes metadata.

Kepler performs attribution at a fixed internal update interval (default: 3 s). All usage metrics and energy deltas within that interval are aggregated before attribution is computed. Because Prometheus scrapes occur independently of Kepler’s internal loop, the exported time series may reflect misalignment when the scrape period is not a multiple of the update interval. This can lead to visible step patterns or oscillations, particularly for dynamic workloads. Despite these limitations, the model provides a coherent and workload-oriented view of node-level energy consumption suitable for cloud-native observability scenarios.

2.4.1.3 Observed Behavior and Limitations

Several studies and code-level inspections reveal that Kepler’s attribution behaviour exhibits systematic limitations that affect accuracy and interpretability. The most

comprehensive empirical evaluation to date, conducted by Pijnacker et al., demonstrates that attribution inaccuracies arise even when node-level power estimation is reliable[50]. Their experiments highlight that idle power is often distributed to containers that are no longer active, including Completed pods, and that dynamic power can be reassigned inconsistently when containers are added or removed. These effects stem from the coupling of process-level accounting with container life-cycle events, which may lag behind cgroup or Kubernetes metadata updates.

Timing mismatches further contribute to attribution artifacts. High-frequency CPU and cgroup statistics are combined with slower telemetry sources such as Redfish, whose update intervals may span tens of seconds. When workload intensity changes during such periods, Kepler may assign disproportionately large or small dynamic energy shares to individual containers. Similar behavior occurs at the Prometheus interface when scrape intervals do not align with Kepler’s internal update loop, producing visible oscillations in the exported time series.

Source-code inspection reinforces these observations. Numerous unimplemented or placeholder sections (e.g. TODO markers) affect key components of the ratio-based attribution model and default configuration paths. In particular, some domains lack explicit usage metrics, leading to fallback behaviour and equal-cost splitting regardless of container activity. GPU attribution relies on a single utilization metric and is therefore sensitive to the temporal behaviour of NVML’s sampling. Together, these issues introduce variability across domains and reduce the transparency of the resulting per-container energy values.

Lifecycle handling also presents challenges. Because container metadata is aggregated from process-level information, short-lived or Completed pods may retain residual energy assignments. Conversely, system processes that cannot be mapped cleanly to Kubernetes abstractions may absorb unassigned power, obscuring the relationship between application behaviour and observed consumption.

Overall, these limitations underscore that Kepler provides a practical but imperfect approximation of container-level energy consumption. The observed behaviour motivates the research gaps identified at the end of this section, particularly the need for finer temporal resolution, explicit handling of idle and residual power, configurable attribution models, and more robust reconciliation across heterogeneous telemetry sources.

2.4.1.4 Kepler v0.10.0

In July 2025, Kepler underwent a substantial architectural redesign with the release of version 0.10.0[51]. The new implementation replaces many of the privileged operations used in earlier versions, removing the need for CAP_BPF or CAP_SYSADMIN and reducing reliance on kernel instrumentation. Instead, Kepler now obtains all workload statistics from read-only /proc and cgroup interfaces. This reduction in privilege requirements significantly improves deployability and security, particularly for managed Kubernetes environments where eBPF- or perf-based approaches are infeasible.

The redesign also introduces a markedly simplified attribution model. Whereas earlier versions combined multiple hardware and software counters (e.g. instructions,

cache misses, GPU utilization) to estimate dynamic energy, Kepler v0.10.0 relies exclusively on CPU time as the usage metric. Node-level dynamic energy is computed by correlating RAPL deltas with aggregate CPU activity, and each workload receives a proportional share of this value based solely on its CPU time fraction. Idle energy is not distributed to containers and instead remains part of a node-level baseline. Containers, processes, and pods are treated as independent consumers drawing from the same active-energy pool, with no dependence on process-derived aggregation.

These changes increase robustness and predictability: the simplified model is easier to reason about, less sensitive to heterogeneous workloads or timing mismatches, and compatible with environments where kernel-level measurement facilities are unavailable. However, the loss of metric flexibility substantially reduces modeling fidelity. Fine-grained distinctions between compute-bound and memory-bound tasks are no longer observable, and the attribution model presumes a strictly linear relationship between CPU time and power consumption. As a result, Kepler v0.10.0 no longer targets high-accuracy energy attribution but instead emphasises operational stability and minimal overhead.

For the purposes of this thesis, Kepler v0.10.0 is relevant primarily as an indication of the project’s strategic shift toward simplicity and broad deployability. Its CPU-time-only model is not suitable as a basis for Tycho, whose objectives require higher temporal resolution, more diverse metric inputs, and explicit handling of domain-level energy contributions. Accordingly, the remainder of this chapter focuses on the behaviour of Kepler v0.9.x, which remains the most representative version for research-oriented attribution discussions.

2.4.2 KubeWatt

KubeWatt is a proof-of-concept exporter developed by Pijnacker as a direct response to the attribution issues uncovered in Kepler.[50, 52] Rather than extending Kepler’s complex pipeline, KubeWatt implements a deliberately narrow but transparent model that focuses on correcting three specific problems: misattribution of idle power, leakage of energy into generic “system processes”, and unstable behaviour under pod churn. It targets Kubernetes clusters running on dedicated servers and assumes that a single external power source per node is available (in the prototype, Redfish/iDRAC).

A central design decision is the strict separation between *static* and *dynamic* power. Static power is defined as the baseline cost of running the node and its control plane in an otherwise idle state. KubeWatt measures or estimates this baseline once and treats it as a constant; it is *not* attributed to containers. Dynamic power is then computed as the difference between total node power and this static baseline and is the only quantity distributed across workloads. Control-plane pods are explicitly excluded from the dynamic attribution set, so their idle consumption remains part of the static term and does not pollute application-level metrics.

To obtain the static baseline, KubeWatt provides two initialization modes. In *base initialization*, the cluster is reduced to an almost idle state (only control-plane components), and node power is sampled for a few minutes. The static power value is computed as a simple average, yielding a highly stable estimate under the test conditions. When workloads cannot be stopped, *bootstrap initialization* fits a regression

model to time series of node power and CPU utilization collected during normal operation. The regression is evaluated at the average control-plane CPU usage to infer the static baseline. This mode is more sensitive to workload characteristics and SMT effects but provides a practical fallback when base initialization is not feasible.

During normal operation, KubeWatt runs in an *estimation mode* that attributes dynamic node power to containers proportionally to their CPU usage. CPU usage is obtained from the Kubernetes metrics API (`metrics.k8s.io`) at node and container level. The denominator explicitly sums only container CPU usage; system processes, cgroup slices, and other non-container activity are excluded by construction. This corrects a key source of error in Kepler, where slice-level metrics and kernel processes could receive non-trivial fractions of node power. Under stable workloads and at the relatively coarse sampling interval used in the prototype, KubeWatt achieves container-level power curves that align well with both iDRAC readings and observed CPU utilisation, and it behaves robustly when large numbers of idle pods are created and deleted.

The scope of KubeWatt is intentionally narrow. It is CPU-only, uses a single external power source per node, assumes that Kubernetes is the only significant workload on the machine, and does not attempt to model GPU, memory, storage, or network energy. It also inherits the temporal limitations of the Kubernetes metrics pipeline and treats Redfish power readings as instantaneous, without explicit latency compensation. Nevertheless, KubeWatt demonstrates that a simple, well-documented ratio model with explicit static–dynamic separation and strict cgroup filtering can eliminate several of Kepler’s most problematic attribution artefacts. These design principles are directly relevant for the attribution redesign pursued in this thesis and inform the requirements placed on Tycho’s more general, multi-source architecture.

2.4.3 Other Tools (Brief Overview)

Beyond Kepler, several tools illustrate the methodological diversity in container- and process-level energy attribution, although they are not central to the Kubernetes-specific challenges addressed in this thesis. Scaphandre[53] provides a lightweight proportional attribution model based exclusively on CPU time and RAPL deltas. Its design emphasises simplicity and portability, offering basic container mapping through cgroups but limited control over sampling behaviour or attribution semantics. SmartWatts[54], by contrast, represents a more sophisticated approach: it builds performance-counter-based models that self-calibrate against RAPL measurements and adapt dynamically to the host system. While effective in controlled environments, SmartWatts requires access to perf events, provides only CPU and DRAM models, and is not deeply integrated with Kubernetes abstractions.

A broader ecosystem of lightweight tools (e.g. CodeCarbon[55] and related library-level estimators) demonstrates further variation in scope and assumptions, but these generally target high-level application profiling rather than system-wide workload attribution. Collectively, these tools highlight a spectrum of design choices (from simplicity and portability to model-driven estimation) but none address the combination of high-resolution telemetry, multi-tenant attribution, and Kubernetes metadata integration that motivates the development of Tycho.

2.4.4 Cross-Tool Limitations Informing Research Gaps

Across the surveyed tools, several structural limitations recur despite substantial differences in design philosophy and implementation. First, temporal granularity remains insufficient: although hardware interfaces such as RAPL support millisecond-level updates, most tools aggregate measurements over multi-second intervals. This obscures short-lived workload behaviour and reduces attribution fidelity, particularly in heterogeneous or bursty environments. Second, all tools depend on telemetry sources whose internal semantics are only partially documented. Ambiguities regarding RAPL domain coverage, NVML power reporting, or BMC-derived node power constrain both the interpretability and the auditability of reported metrics, reinforcing the black-box character of current measurement pipelines.

Idle-power handling presents a further source of inconsistency. Tools differ widely in how idle power is defined, whether it is attributed, and to whom. These choices are often implicit, undocumented, or constrained by implementation artefacts, leading to attribution patterns that are difficult to interpret or reproduce. Multi-domain coverage is similarly limited: existing tools focus primarily on CPU and, to a lesser extent, DRAM or GPU consumption, leaving storage, networking, and other subsystems unmodelled despite their relevance to node-level energy use.

Metadata lifecycle management also emerges as a common limitation. Rapid container churn, transient pods, and the interaction between Kubernetes and cgroup identifiers can produce incomplete or stale workload associations, affecting attribution stability. Finally, attribution models themselves are typically rigid. Most tools hard-code a specific proportionality assumption (commonly CPU time or a single hardware counter) and provide limited support for calibration, uncertainty quantification, or alternative modelling philosophies.

Taken together, these limitations reveal structural gaps in current approaches to container-level energy attribution. They motivate the need for tools that combine high-resolution telemetry handling, transparent and configurable attribution logic, robust metadata management, and principled treatment of uncertainty. The next section distills these observations into concrete research gaps that inform the design objectives of Tycho.

2.5 Research Gaps

This section synthesises the findings from the preceding analyses of telemetry sources, temporal behaviour, and existing tools. Across these perspectives, a set of structural limitations emerges that fundamentally constrains accurate and explainable energy attribution in Kubernetes environments. These limitations arise at three intertwined layers: the measurement interfaces exposed by hardware and kernel subsystems, the attribution models built on top of these measurements, and the operational context in which Kubernetes workloads execute. Taken together, they demonstrate the absence of a framework that provides high temporal precision, transparent modelling assumptions, and robustness to container lifecycle dynamics. The gaps identified below define the technical requirements that motivate the design of Tycho.

(1) Measurement Gaps: Temporal Resolution and Telemetry Semantics

Existing tools do not exploit the full temporal capabilities of modern hardware telemetry. Interfaces such as RAPL offer fast, reliable update frequencies, yet tools operate on fixed multi-second loops, causing short-lived or bursty activity to be temporally averaged away. Moreover, latency mismatches between high-frequency utilization signals (e.g. cgroups, perf counters) and low-frequency power interfaces (e.g. Redfish/BMC) introduce structural attribution errors that are not explicitly modelled or corrected.

A related issue is the opacity of hardware telemetry. RAPL, NVML, and BMC power sensors provide indispensable data, but their domain boundaries, averaging windows, and internal update behaviour are insufficiently documented. This prevents rigorous interpretation of reported values and inhibits the development of calibration or uncertainty models. Finally, measurement coverage remains incomplete: while CPU and DRAM domains are widely supported, no standardised telemetry exists for storage, networking, or other subsystems. Current tools treat these components either implicitly (as part of “platform” power) or not at all.

(2) Attribution Model Gaps: Rigidity, Idle Power, and Domain Consistency

Current attribution models rely on rigid proportionality assumptions (typically CPU time, instructions, or a single hardware counter) without considering alternative modelling philosophies. Idle power remains a persistent source of inconsistency: tools variously divide it evenly, proportionally, or not at all, often without documenting the rationale. These choices have substantial effects on per-container energy values, particularly in lightly loaded or heterogeneous systems.

At the domain level, attribution methods are not unified. CPU, DRAM, uncore, GPU, and platform energy are treated through incompatible heuristics, and many domains fall back to equal distribution when no clear usage signal is defined. None of the surveyed tools quantify uncertainty, despite relying on noisy, coarse, or undocumented telemetry sources. As a result, attribution outputs appear deterministic even when they rest on incomplete or ambiguous measurement assumptions.

(3) Metadata and Lifecycle Gaps: Churn, Timing, and Virtualization

Container-level attribution requires consistent mapping between processes, cgroups, and Kubernetes metadata. Existing tools struggle in scenarios with rapid container churn, ephemeral or Completed pods, and multi-process containers. Mismatches between metadata refresh cycles and metric sampling lead to stale or missing associations, which propagate into attribution artefacts.

Energy attribution inside virtual machines remains essentially unsolved. No standard mechanism exists for exposing host-side telemetry to guest systems in a way that preserves temporal alignment and attribution consistency. The limited QEMU-based passthrough available in Scaphandre is not generalisable, and conceptual proposals (e.g. Kepler’s hypercall mechanism) remain unimplemented. Given the prevalence of cloud-hosted Kubernetes clusters, this constitutes a major practical limitation.

(4) Usability, Transparency, and Operational Gaps

For most tools, implementation assumptions, fallback paths, and attribution decisions are implicit. Users cannot easily distinguish measured values from estimated ones, nor identify the assumptions underlying attribution outputs. This lack of transparency reduces trust and complicates debugging.

Operational constraints further restrict applicability. Tools that require privileged kernel instrumentation (eBPF, `perf_event_open`) are unsuitable for many production clusters, while tools designed around unprivileged access often sacrifice modelling fidelity. At the same time, developers, operators, and researchers have fundamentally different observability needs, yet existing tools optimise for only one audience at a time. None provide configurable attribution modes or role-specific abstractions.

(5) Missing Support for Calibration and Validation

Beyond isolated exceptions, existing tools provide limited mechanisms for systematic calibration or validation of their attribution models. KubeWatt is one of the few systems that performs explicit baseline calibration, offering both an idle-power measurement mode and a statistical fallback for environments without idle windows. Kepler offers no structured calibration workflow, and its estimator models lack reproducible training procedures. SmartWatts introduces online model recalibration but focuses narrowly on performance-counter regression, leaving node-level baselines, multi-domain alignment, and external ground-truth integration unaddressed.

Across all tools, there is no standardized path to incorporate external measurements (for example from wall-power sensors or BMC-level telemetry) to validate or refine model behaviour. Idle power is seldom isolated as a first-class parameter, attribution error is rarely quantified, and no system provides uncertainty estimates that reflect measurement or modelling limitations. Without such calibration and validation capabilities, attribution accuracy cannot be assessed, corrected, or improved over time—an essential requirement for any system intended to provide trustworthy, high-resolution energy insights in Kubernetes environments.

2.6 Summary

The analyses in this chapter reveal that modern server platforms provide a heterogeneous and only partially documented set of telemetry interfaces whose temporal and semantic properties fundamentally constrain container-level energy attribution. Hardware-integrated sources such as RAPL and NVML expose valuable domain-level energy information but differ substantially in update behaviour, averaging semantics, and domain completeness. Out-of-band telemetry via Redfish provides stable whole-system measurements but at coarse and irregular temporal granularity. Software-exposed metrics offer fine-grained visibility into workload behaviour, yet they measure utilisation rather than power and depend entirely on polling strategies for temporal interpretation.

Temporal irregularities, internal averaging, and undocumented sensor behaviour reduce the effective precision of all telemetry sources, especially when attempting to capture short-lived workload dynamics. Existing tools aggregate these heterogeneous signals using fixed multi-second sampling loops and rigid proportionality

assumptions, which leads to systematic attribution artefacts. Idle power is treated inconsistently across systems, residual power is frequently conflated with workload activity, and multi-domain attribution remains fragmented in both semantics and implementation. Metadata churn and asynchronous refresh cycles further complicate the mapping between processes, containers, and Kubernetes abstractions, reducing the stability and interpretability of attribution outputs.

The cross-tool evaluation confirms these structural limitations. Kepler provides broad telemetry integration but struggles with timing mismatches, incomplete domain semantics, and opaque idle handling. Kubewatt demonstrates the importance of explicit baseline separation and cgroup filtering, yet remains limited to single-domain CPU-based estimation. Other tools illustrate a spectrum of design choices but do not address the combined challenges of high-frequency telemetry, multi-domain attribution, container lifecycle dynamics, and Kubernetes integration.

Together, these findings motivate the need for a framework that provides high temporal fidelity, transparent modelling assumptions, unified domain treatment, explicit handling of idle and residual energy, and robust metadata reconciliation. These requirements form the conceptual and architectural foundations developed in [Chapter 3](#), which introduces the methodological principles guiding the design of Tycho.

Chapter 3

Conceptual Foundations of Container-Level Power Attribution

Energy attribution explains how workloads contribute to the power consumed by a node. Hardware exposes only aggregate energy behaviour, so attribution constructs a model that distributes this aggregate across multiple sources of activity. The aim of this chapter is to establish the conceptual basis for such modelling. It introduces the abstractions needed to reason about workloads, execution units, temporal structure, and observation windows. It also presents the principles that constrain any defensible attribution model and identifies the interactions that make attribution non-trivial. The discussion is purely conceptual and does not rely on empirical detail from [Chapter 2](#). These concepts form the foundation for the system requirements developed later in the chapter and for the architectural design presented in [Chapter 4](#).

3.1 Nature and Purpose of Power Attribution

Power attribution is a modelling activity. Hardware reports only aggregate power or energy, and attribution constructs an explanation that distributes this aggregate across the workloads running on the node. The model is necessarily reactive because measurements become available only after the underlying activity has occurred. Attribution therefore explains past energy behaviour rather than providing realtime insight, although the resulting information can support optimisation and accountability.

Attribution is useful because it reveals how different workloads contribute to dynamic power consumption. This enables comparisons between workloads, supports evaluation of deployment or scheduling strategies, and provides interpretable information for higher level policy decisions.

For the purposes of this chapter, a workload is defined as a logical entity that groups one or more execution units into a stable attribution target. Execution units may include processes, threads, containers, virtual machines, or service components. Their membership can change over time, but the workload identity persists as the object to which energy is assigned.

3.2 Workload Identity and Execution Boundaries

Energy attribution operates on workload identities rather than on individual execution units. Execution units such as processes, threads, or container instances appear and terminate independently, often with lifetimes that do not align with observation windows. Their behaviour may overlap, interleave, or succeed one another in ways that complicate any direct mapping between activity and energy. A workload need not coincide with a single application; it may represent a subset of an application, a combination of cooperating services, or a logical grouping chosen purely for attribution.

Attribution therefore relies on a stable abstraction that groups such units into coherent entities. Orchestration frameworks, including systems such as Kubernetes, illustrate this principle by associating container instances with higher level constructs such as pods or services. The attribution target is the logical workload, not the transient units that realise it at any moment.

Short lived execution units raise specific challenges. Some may terminate between consecutive measurements, and their activity may be only partially observable. Others may overlap in time while belonging to the same workload identity. A consistent attribution model must track these changing memberships without losing energy when units disappear or double counting energy when multiple units contribute concurrently. Stable workload identities provide the conceptual basis for such tracking.

3.3 Principles of Workload-Level Energy Attribution

Several principles constrain how node-level energy can be attributed to workloads. These principles are intertwined and reflect structural properties of shared hardware, the limits of observability, and the semantics of available metrics. Some depend on how measurements are structured in time, while others remain independent of temporal detail. The temporal aspects are developed further in § 3.4, but the principles themselves abstract from any specific system and define the conditions that any defensible attribution model must satisfy.

3.3.1 Aggregated Hardware Activity

Hardware exposes only aggregate power or energy for the node or for coarse hardware domains. It does not reveal how much of this consumption originates from any specific workload. Attribution therefore begins with a single observable quantity that reflects the combined activity of all execution units. Any per workload assignment is an inferred decomposition of this aggregate and must remain consistent with the measured total.

3.3.2 Domain Decomposition

Total system power is composed of contributions from several hardware domains, such as compute, memory, accelerators, storage, and platform circuitry. These domains respond differently to workload behaviour, and their relative impact varies across systems. Attribution must therefore reason at the domain level before assigning energy to workloads. Without such decomposition, the resulting assignments

would combine unrelated forms of activity and obscure the link between workload characteristics and observed power.

3.3.3 Conservation

Node-level energy is a fixed quantity within any observation window. An attribution model must assign energy to workloads in a way that is consistent with this total. The sum of all assigned energy, including any explicitly modelled background components, must equal the measured dynamic energy. Violations of conservation indicate that the model is incomplete or internally inconsistent.

3.3.4 Static–Dynamic Separation

System power consists of a baseline component that persists regardless of workload activity and a dynamic component induced by the workloads. Attribution concerns only the dynamic portion, so the baseline must be treated explicitly rather than absorbed into workload assignments. Any remaining unexplained energy must appear as a residual component and must not be redistributed silently across workloads.

3.3.5 Uncertainty and Non-Uniqueness

Workload-level energy attribution has no unique ground truth. Limited observability, asynchronous measurements, and interactions between hardware domains allow multiple decompositions of the same aggregate energy to be consistent with the measurements. A defensible attribution model must acknowledge this non-uniqueness and avoid implying precision that the underlying information does not support.

3.3.6 Dependence on Metric Fidelity

Attribution quality depends on the fidelity of the metrics that describe workload activity. Each metric has specific semantics, precision, and temporal resolution, and these properties determine how reliably the metric reflects the underlying hardware behaviour. An attribution model must therefore interpret metrics consistently and acknowledge that limited or coarse measurements constrain the accuracy of any inferred energy assignments.

Hardware subsystems are shared and not fully partitionable. Execution units contend for caches, memory controllers, and shared frequency or power budgets, and these interactions alter the relation between observed activity and actual power consumption. Such interference reduces the ability of any metric to isolate per workload effects and increases attribution uncertainty. A defensible model must incorporate these limitations when relating activity signals to domain level energy.

3.4 Temporal and Measurement Foundations

Attribution depends not only on which quantities are measured but also on when they are measured. Telemetry sources observe system behaviour at different times, with different implicit meanings, and with no inherent coordination. A clear temporal framework is therefore required to interpret workload activity and relate it to the energy observed at the node.

Observation Windows

Attribution operates on observation windows. A window integrates power and activity over a chosen duration and provides the temporal unit within which energy is assigned to workloads. All attribution reasoning occurs within these windows, so their boundaries determine which activity contributes to the measured energy and how temporal ambiguity affects attribution accuracy.

3.4.1 Sampling vs Event-Time Perspectives

Sampling records system state at fixed intervals, independent of when the underlying activity changes. Event time reflects the moment when the activity occurs or when a telemetry source updates its value. These perspectives rarely coincide. If a workload is active between two samples, the sampled values do not reveal when within the interval the activity occurred. Misalignment between when work happens and when it is observed creates ambiguity about how activity should be mapped into the observation window.

3.4.2 Clock Models and Temporal Ordering

Attribution requires a consistent ordering of events and measurements. Realtime clocks track wall clock time but may jump when synchronised, which breaks temporal ordering. Monotonic clocks advance continuously and therefore provide a stable basis for placing events on a time axis. A coherent attribution model relies on such ordering to determine which activity belongs to which observation window and to avoid artefacts caused by clock adjustments.

3.4.3 Heterogeneous Metric Sources

Telemetry originates from sources with different update cycles and semantics. Hardware counters accumulate events continuously and reveal activity only when read. Operating system accounting updates periodically according to scheduler behaviour. Device telemetry and external power interfaces publish measurements based on internal schedules. These sources do not share cadence, precision, or timestamp meaning. Their values represent different kinds of temporal information, and none can be assumed to align with the others.

3.4.4 Delay, Jitter, and Temporal Uncertainty

Measurements do not appear at the moment the underlying behaviour occurs. Observation delay arises when a metric is read after the activity has taken place. Publication delay arises when a telemetry source exposes an updated value only after internal processing. Jitter denotes variations in these delays. Because different sources exhibit different forms of delay, the temporal relation between activity and observed energy is uncertain. This uncertainty limits the precision with which activity can be linked to energy within an observation window.

3.4.5 Temporal Alignment of Asynchronous Signals

Attribution requires heterogeneous signals to be interpreted within the same observation window even though they arrive at different times and represent different temporal semantics. Some values describe cumulative changes, others instantaneous states, and others discrete events. A temporal alignment model must reconcile these signals without assuming true synchronisation. The goal is not to remove temporal uncertainty but to structure it so that attribution remains coherent and consistent with the measured energy.

3.5 Conceptual Attribution Frameworks

Because hardware exposes only aggregate energy, several modelling philosophies can be used to distribute this energy across workloads. These frameworks differ in how they relate activity metrics to energy and in how they treat uncertainty. None yields a unique solution, since the same measurements can support multiple plausible decompositions. Instead, each framework reflects a particular set of priorities, such as stability, fairness, or explanatory power, and provides a structured interpretation of the same underlying observations.

3.5.1 Proportional Attribution

Proportional attribution assigns energy to workloads in proportion to an observed activity metric, such as CPU time or memory access volume. Its appeal lies in its simplicity and interpretability. However, different metrics emphasise different forms of behaviour, and proportionality with respect to one metric does not imply proportionality with respect to another. The choice of metric therefore has direct consequences for the resulting attribution.

3.5.2 Shared-Cost Attribution

Shared-cost attribution distributes some portion of the dynamic energy uniformly or proportionally across all active workloads, independent of their individual activity levels. This approach emphasises stability and fairness and is often used when activity metrics are incomplete or unreliable. Its limitation is that it may obscure relationships between workload behaviour and energy consumption, since unexplained costs are not tied to specific activity.

3.5.3 Residual and Unattributed Energy

Some energy cannot be explained by available metrics or by direct workload activity. Subsystems without meaningful utilisation signals, background services, and asynchronous events contribute to a residual component. Treating this component explicitly preserves conservation and avoids distorting the energy assigned to observable activity. Residual energy also delineates the boundary between explainable and unexplained behaviour within an attribution model.

3.5.4 Model-Based or Hybrid Attribution

Model-based or hybrid attribution combines several activity signals into an explicit model of energy consumption. Such a model may weight metrics from different domains, encode domain-specific relationships, or blend proportional and shared-cost

components. It does not attempt to establish strict causality, but it treats the mapping from activity to energy as a structured function rather than a single proportional rule. The quality of the resulting attribution depends on how well the model captures the relevant relationships and on how stable these relationships remain across workloads and system states.

3.5.5 Causal or Explanatory Attribution

Causal or explanatory attribution attempts to relate changes in workload activity to changes in power consumption. It seeks to model relationships between metrics and energy rather than applying proportionality directly. This approach can capture more nuanced behaviour, but its accuracy depends on metric fidelity and on the stability of the relationship between activity and power. Limited observability and shared subsystem interactions restrict the strength of causal inferences.

Link to System Requirements

These frameworks illustrate the range of assumptions an attribution model may adopt. They highlight the need for transparent modelling choices, consistent interpretation of metrics, explicit treatment of residual components, and temporal coherence when relating activity to energy. In practice, their behaviour is further constrained by shared hardware, domain interactions, and temporal misalignment, which shape how any chosen framework behaves under real workloads. These combined effects are examined in § 3.6 and motivate the system requirements developed in § 3.7.

3.6 Interactions and Complications

The principles and temporal concepts introduced above interact in ways that make workload-level attribution fundamentally approximate. These interactions arise from shared hardware, limited observability, asynchronous measurements, and the structure of workloads themselves.

Combined Effects of Shared Hardware and Temporal Misalignment

Shared subsystems create interference that couples the activity of different workloads. Contention for caches, memory controllers, or shared power and frequency budgets alters the relation between observed activity and actual energy consumption. Temporal misalignment compounds this effect. When activity and power are observed at different times and with different delays, the ambiguity introduced by interference cannot be resolved by sampling alone. The combined effect limits the extent to which per workload contributions can be isolated.

Cross-Domain Interactions

Hardware domains are not independent. Changes in compute activity can influence memory behaviour or power states, and accelerators may shift platform level consumption. These interactions mean that energy attributed to one domain may reflect behaviour originating in another. Attribution must therefore operate under the constraint that domain boundaries provide structure but not complete separation.

Attribution as an Inverse Problem

Because only aggregate energy is measured, attribution requires inferring per workload contributions from incomplete and asynchronous observations. This inference is an inverse problem with multiple admissible solutions. Limited metric fidelity, shared hardware behaviour, and temporal uncertainty restrict how precisely activity can be mapped to energy. A coherent attribution model acknowledges these limitations and structures them explicitly rather than treating them as noise.

3.7 Conceptual Challenges and System Requirements

The challenges identified above arise from shared hardware behaviour, asynchronous and heterogeneous measurements, limited metric fidelity, and volatile workload lifecycles. Any attribution system must address these challenges within a coherent conceptual framework. The requirements formulated in this section follow directly from the principles and temporal foundations established earlier and specify the conditions that an attribution model shall satisfy.

3.7.1 Requirement: Temporal Coherence

The system *must* maintain coherent temporal structure across all telemetry sources. Measurements that arrive with differing delays, cadences, or timestamp semantics *shall* be placed on a consistent time axis and related correctly to the boundaries of the observation window. The system *should* tolerate irregular update patterns without introducing artefacts, and it *may* employ temporal reconstruction provided that ordering and conservation are preserved.

3.7.2 Requirement: Domain-Level Consistency

The system *must* decompose node-level energy into meaningful hardware domains before workload-level assignment. Each domain *shall* be treated using internally consistent rules, and the system *must not* combine unrelated forms of activity into a single attribution pathway. When direct observability is incomplete, the system *should* incorporate explicit residual modelling, and it *may* use domain specific strategies when justified by domain characteristics.

3.7.3 Requirement: Cross-Domain Reconciliation

The system *must* reconcile energy information from different hardware domains in a coherent manner. When domain-level signals disagree, the reconciliation strategy *shall* be explicit and internally consistent rather than relying on implicit priority rules. The system *should* expose when domains provide conflicting indications about energy usage and clarify how such conflicts influence per workload assignments. Any reconciliation *must not* violate conservation across domains or undermine the stability of workload-level attribution.

3.7.4 Requirement: Consistent Metric Interpretation

The system *must* interpret activity metrics in a stable and coherent manner. Metrics that differ in semantics, resolution, or precision *shall* not be combined without clear conceptual justification. The system *must not* allow the meaning of a metric to

vary across time or domains. It *should* treat metric limitations explicitly, and it *may* disregard metrics whose quality does not support meaningful attribution.

3.7.5 Requirement: Transparent Modelling Assumptions

All assumptions used to relate activity to energy *must* be explicit. The basis on which energy is distributed *shall* be interpretable, including the choice of attribution framework, the handling of idle and residual energy, and any fallback behaviour in the presence of incomplete metrics. The system *should* separate measured quantities from inferred quantities to avoid ambiguity, and it *may* expose configurable modelling options provided they do not violate consistency or conservation.

3.7.6 Requirement: Lifecycle-Robust Attribution

The system *must* remain consistent under workload churn. Execution units that appear or terminate within an observation window *shall* be tracked in a way that avoids both loss of energy and double counting. Workload identities *must* remain stable even when their underlying execution units change. The system *should* support overlapping lifecycles and transient units without degrading attribution quality, and it *may* use buffering or reconciliation strategies when necessary.

3.7.7 Requirement: Uncertainty-Aware Attribution

The system *should* acknowledge uncertainty arising from limited observability, shared hardware behaviour, and temporal misalignment. It *shall* avoid implying precision that the measurements do not support. Where feasible, it *should* represent unexplained energy explicitly rather than absorbing it into unrelated workloads. Any handling of uncertainty *must not* violate conservation or temporal ordering.

Link to Architectural Considerations

These requirements imply that an attribution system must provide mechanisms for temporal alignment, domain level reasoning, stable metric interpretation, explicit residual handling, and robust tracking of workload identities. They form the basis for the architectural design presented in [Chapter 4](#).

3.8 Summary

This chapter introduced the conceptual foundations of workload-level energy attribution. It defined workloads and execution units, presented the principles that govern how aggregate energy can be decomposed, and developed the temporal and measurement concepts required to interpret heterogeneous telemetry. It also showed how shared hardware behaviour, metric limitations, and asynchronous observations interact to make attribution inherently approximate. These considerations led to a set of system requirements that any attribution model must satisfy. The next chapter builds on these requirements and introduces an architecture designed to meet them.

Chapter 4

System Architecture

4.1 Guiding Principles

Tycho's architecture is shaped by a small set of foundational principles that govern how measurements are interpreted, combined and ultimately attributed. These principles are architectural in nature: they articulate *how* the system must reason about observations, not *how* it is implemented. They establish the conceptual baseline that the subsequent sections refine in detail.

- **Accuracy-first temporal coherence.** Architectural decisions prioritise the reconstruction of temporally coherent views of system behaviour. Observations are treated as samples of an underlying physical process, and the architecture is designed to preserve their temporal meaning rather than force periodic alignment.
- **Domain-aware interpretation.** Metric sources differ in semantics and cadence. The architecture respects these differences and avoids imposing artificial synchrony or uniform sampling behaviour across heterogeneous domains.
- **Transparency of assumptions.** All modelling assumptions must be explicit, inspectable and externally visible. The architecture prohibits implicit corrections or hidden inference steps that would obscure how measurements lead to attribution results.
- **Uncertainty as a first-class concept.** Missing, stale or delayed information is treated as uncertainty rather than error. Architectural components convey and preserve uncertainty so that later stages may interpret it correctly.
- **Separation of observation, timing and attribution.** Measurement collection, temporal interpretation and energy attribution form distinct architectural layers. This separation prevents cross-coupling, clarifies responsibilities and ensures that improvements in one layer do not implicitly alter the behaviour of others.

4.2 Traceability to Requirements

The architectural structure introduced in this chapter provides a direct response to the requirements established in § 3.7. Each requirement class corresponds to specific architectural mechanisms, ensuring that the system design follows from formal constraints rather than implementation convenience.

Requirement: Temporal Coherence. Satisfied through event-time reconstruction, independent collector timelines, and window-based temporal alignment.

Requirement: Domain-Level Consistency. Addressed by per-domain interpretation layers, domain-aware handling of metric semantics, and explicit decomposition of node-level signals.

Requirement: Cross-Domain Reconciliation. Supported by a unified temporal model, window-level aggregation boundaries, and explicit reconciliation logic across domains during analysis.

Requirement: Consistent Metric Interpretation. Ensured by separating observation from interpretation, enforcing stable metric semantics within each domain, and isolating heterogeneous metrics into dedicated processing paths.

Requirement: Transparent Modelling Assumptions. Realised through explicit modelling steps, external visibility of assumptions, and separation between measured and inferred quantities.

Requirement: Lifecycle-Robust Attribution. Enabled by metadata freshness guarantees, stable process–container mapping, and attribution rules that remain valid under workload churn.

Requirement: Uncertainty-Aware Attribution. Supported by explicit treatment of stale or missing data, uncertainty propagation in window evaluation, and preservation of unexplained residuals.

4.3 High-Level Architecture

4.3.1 Subsystem Overview

Tycho is organised into a small set of subsystems, each with a distinct responsibility. The following overview introduces these subsystems without yet describing their interactions.

Timing engine. Defines the temporal reference used throughout the system and provides the notion of analysis windows. It is responsible for deciding when a window is complete and ready to be evaluated.

Metric collectors. Acquire observations from hardware and software sources and attach timestamps in the global temporal reference. They expose their output as streams of samples without coordinating with each other.

Metadata subsystem. Maintains the mapping between operating-system level entities and workload identities. It tracks relationships between processes, cgroups, containers and pods over time.

Buffering and storage layer. Stores recent observations in bounded histories so that samples relevant to a given window can be retrieved efficiently. It treats metric streams and metadata as read-mostly records.

Analysis engine. Interprets temporally aligned observations and metadata to produce energy estimates for each analysis window. It forms the logical bridge between

measurement and attribution.

Calibration framework. Derives auxiliary information about typical delays, update patterns and idle behaviour. It produces constraints and characterisations that other subsystems rely on for interpretation.

Exporter. Exposes the results of the analysis engine to external monitoring systems as metrics ready for scraping and downstream processing.

4.3.2 Dataflow and Control Flow

Before Tycho enters normal operation, external calibration scripts determine approximate delay characteristics for all relevant metric sources. At startup, Tycho’s internal calibration component derives suitable polling frequencies for metric collectors and metadata acquisition, providing the initial operating parameters for the system.

During runtime, control flow originates in the timing engine. It triggers each collector according to its calibrated polling frequency, but collectors operate independently: they sample their respective domains without synchronising with each other, and each sample is appended to the appropriate buffer together with its timestamp and quality indicators. In parallel, metadata acquisition proceeds on its own schedule, refreshing the mappings between processes, cgroups and workload identities in the metadata cache.

The timing engine also governs when analysis occurs. At regular intervals—constituting fixed-length analysis windows—it initiates a new evaluation cycle irrespective of how many samples have been collected. Each cycle begins by estimating idle behaviour for the relevant hardware domains based on the buffered observations. The analysis engine then interprets the buffered metric samples, the metadata cache and the idle characterisations, taking calibrated delays into account when reconstructing the temporal structure of the window. It produces per-window energy estimates for all domains and workloads.

Once analysis completes, the exporter publishes the resulting metrics in a form suitable for ingestion by external monitoring systems. Calibration remains active in the background throughout the system’s lifetime: it observes collector behaviour and derived quantities over longer time spans and refines its characterisations when needed, informing both the timing and analysis components without altering any collected data.

4.4 Temporal Model and Timing Engine

Tycho’s temporal architecture provides a coherent framework for relating heterogeneous metric streams to fixed-duration analysis windows. It establishes a common time base, defines how collectors operate, and specifies how windows are formed and interpreted. The model is intentionally simple: collectors run independently, timestamps reflect poll time, and all temporal reasoning occurs during analysis.

4.4.1 Event-Time Model and Timestamp Semantics

Tycho adopts a single monotonic time base for all temporal coordination. Collectors timestamp each sample at the moment of observation; these timestamps reflect

FIGURE 4.1: Dataflow and control flow in Tycho. Metric sources feed collectors and the metadata subsystem, which populate the buffering layer and metadata cache. The timing engine inspects buffered data to define analysis windows and trigger evaluation. The analysis engine performs attribution for each window and the exporter publishes the resulting metrics. Calibration observes long-term behaviour and feeds auxiliary information back into timing and analysis.

poll time, not the physical instant at which the underlying hardware event occurred. Event time is therefore a modelling construct used by the analysis engine when interpreting delay, freshness and update behaviour.

This separation keeps collectors lightweight and domain-agnostic. Each collector reports only what it directly observes; the analysis engine later interprets these timestamps in context, using calibration-derived delay characteristics to approximate underlying temporal structure.

4.4.2 Independent Collector Schedules

Tycho employs independent, domain-aware sampling schedules. During startup the timing engine configures one schedule per collector, after which each collector operates autonomously on its own periodic trigger. No global poll loop exists and collectors do not synchronise with one another. They push samples only when a new observation is available.

This decoupling avoids artificial temporal alignment and preserves each domain's intrinsic update behaviour. Collector timestamps are placed directly on the global monotonic time axis, allowing later reconstruction without imposing shared cadence or shared sampling semantics.

FIGURE 4.2: Conceptual relation between physical behaviour (event time) and observations recorded at poll time. Tycho records poll-time timestamps and interprets them as approximations of underlying event-time behaviour in the analysis phase.

FIGURE 4.3: Independent sampling schedules for different collectors on a shared time axis. Each collector operates on its own cadence without synchronisation, and samples are later aligned only at the level of analysis windows.

4.4.3 Window Construction and Analysis Triggering

Analysis proceeds in fixed-duration windows defined solely by periodic triggers from the timing engine. If the triggers occur at monotonic times T_0, T_1, T_2, \dots , window W_i is the half-open interval $[T_i, T_{i+1})$. Window duration is nominally constant but may drift slightly, which is acceptable for attribution.

When a window closes, the analysis engine performs two conceptual phases:

- (i) *idle characterisation*, using long-term buffered history across all relevant domains, and
- (ii) *window reconstruction and attribution*, using all samples whose timestamps precede T_{i+1} .

Only energy for the current window is attributed and exported, but additional historical samples inform delay interpretation, idle estimation and interpolation.

Tycho treats domains asymmetrically: CPU and software metrics are always required; GPU and Redfish domains contribute when available. Samples too old to fall within the current window do not contribute directly but may still inform background characterisation. Windows remain valid even when optional domains are absent.

A sample is considered stale relative to a window when its poll timestamp predates T_i by more than a domain-specific tolerance. Stale samples are ignored for direct reconstruction but do not invalidate the window.

FIGURE 4.4: Analysis window W_i defined by two successive analysis trigger times. Samples inside the window contribute directly to reconstruction, while samples outside may still inform background characterisation but are not attributed to W_i .

FIGURE 4.5: Conceptual comparison between Kepler and Tycho timing. Kepler uses a synchronous polling interval for most domains and reuses slower Redfish readings across multiple intervals; export may occur on a different cadence. Tycho employs independent collectors and defines attribution strictly in terms of analysis windows, with export immediately following each window.

4.4.4 Comparison to Kepler Timing Model

Kepler employs a synchronous timing model in which all metric domains (except Redfish) are sampled in a single periodic poll cycle. A fixed-length polling interval defines both the sampling cadence and the logical unit of attribution. Redfish updates occur at a much slower pace and the most recent Redfish value is reused across multiple intervals. Export occurs at a separate cadence, which may not match the attribution interval.

Tycho diverges fundamentally: collectors run independently, windows are defined by analysis triggers rather than poll cycles, the model permits heterogeneous update patterns, and export occurs immediately after each attribution step. This structure enables finer temporal resolution, avoids dependence on synchronous poll-time alignment, and eliminates inconsistencies between data collection and publishing intervals.

Diagram placeholder: Tycho vs. Kepler timing Side-by-side schematic:

FIGURE 4.6: Conceptual view of GPU power as a continuous signal, periodically updated internal NVML values, and Tycho’s phase-aware sampling aligned to these updates. No specific update interval or magnitude is implied.

FIGURE 4.7: Conceptual mapping ladder from operating-system processes to Kubernetes-level workload identities. Tycho’s metadata subsystem maintains these relationships over time to support container-level attribution.

4.9 Architectural Trade-Offs and Alternatives Considered

- 4.9.1 Alternative Timing Designs
 - * - Asynchrony is expected and preserved.
- 4.9.2 Alternative Attribution Strategies
- 4.9.3 Complexity vs Accuracy Considerations

4.10 Summary

Chapter 5

Placeholder for WIP sections

5.1 System Environment for Development, Build and Debugging

This section documents the environment used to develop, build, and debug *Tycho*; detailed guides live in [56].

5.1.1 Host Environment and Assumptions

All development and debugging activities for *Tycho* were performed on bare-metal servers rather than virtualized instances. Development matched the evaluation target and preserved access to hardware telemetry such as RAPL, NVML, and BMC Redfish. The host environment consisted of Lenovo ThinkSystem SR530 servers (Xeon Bronze 3104, 64 GB DDR4, SSD+HDD, Redfish-capable BMC).

The systems ran Ubuntu 22.04 with a Linux 5.15 kernel. Full root access was available and required in order to access privileged interfaces such as eBPF. Kubernetes was installed directly on these servers using PowerStack[1], and served as the platform for deploying and testing *Tycho*. Access was via VPN and SSH within the university network.

5.1.2 Build Toolchain

Two complementary workflows are used: a dev path (local build, run directly on a node for interactive debugging) and a deploy path (build a container image, push to GHCR, deploy as a privileged DaemonSet via *PowerStack*).

5.1.2.1 Local builds

The implementation language is Go, using `go version go1.25.1` on `linux/amd64`. The `Makefile` orchestrates routine tasks. The target `make build` compiles the exporter into `_output/bin/<os>_<arch>/kepler`. Targets for cross builds are available for `linux/amd64` and `linux/arm64`. The build injects version information at link time through `LDFLAGS` including the source version, the revision, the branch, and the build platform. This supports traceability when binaries or images are compared during experiments.

5.1.2.2 Container images

Container builds use Docker Buildx with multi arch output for `linux/amd64` and `linux/arm64`. Images are pushed to the GitHub Container Registry under the project repository. For convenience there are targets that build a base image and optional variants that enable individual software components when required.

5.1.2.3 Continuous integration

GitHub Actions produces deterministic images with an immutable commit-encoded tag, a time stamped dev tag, and a latest for `main`. Builds are triggered on pushes to the main branches and on demand. Buildx cache shortens builds without affecting reproducibility.

5.1.2.4 Versioning and reproducibility

Development proceeds on feature branches with pull requests into `main`. Release images are produced automatically for commits on `main`. Development images are produced for commits on `dev` and for feature branches when needed. Dependency management uses Go modules with a populated `vendor/` directory. The files `go.mod` and `go.sum` pin the module versions, and `go mod vendor` materializes the dependency tree for offline builds.

5.1.3 Debugging Environment

The debugger used for *Tycho* is **Delve** in headless mode with a Debug Adapter Protocol listener. This provides a stable front end for interactive sessions while the debugged process runs on the target node. Delve was selected because it is purpose built for Go, supports remote attach, and integrates reliably with common editors without altering the build configuration beyond standard debug symbols.

5.1.3.1 Remote debugging setup

Debug sessions are executed on a Kubernetes worker node. The exporter binary is started under Delve in headless mode with a DAP listener on a dedicated TCP port. The workstation connects over an authenticated channel. In practice an SSH tunnel is used to forward the listener port from the node to the workstation. This keeps the debugger endpoint inaccessible from the wider network and avoids additional access controls on the cluster. To prevent metric interference the node used for debugging excludes the deployed DaemonSet, so only the debug instance is active on that host.

5.1.3.2 Integration with the editor

The editor is configured to attach through the Debug Adapter Protocol. In practice a minimal launch configuration points the adapter at the forwarded listener. Breakpoints, variable inspection, step control, and log capture work without special handling. No container specific extensions are required because the debugged process runs directly on the node.

The editor attaches over the SSH-forwarded DAP port; the inner loop is build locally with `make`, launch under Delve with a DAP listener, attach via SSH, inspect, adjust,

repeat. When the goal is to validate behavior in a cluster setting rather than to step through code, the deploy oriented path is used instead. In that case the image is built and pushed, and observation relies on logs and metrics rather than an attached debugger.

5.1.3.3 Limitations and challenges

Headless remote debugging introduces some constraints. Interactive sessions depend on network reachability and an SSH tunnel, which adds a small amount of latency. The debugged process must retain the privileges needed for eBPF and access to hardware counters, which narrows the choice of where to run sessions on multi tenant systems. Running a second exporter in parallel on the same node would distort measurements, which is why the DaemonSet is excluded on the debug host. Container based debugging is possible but less convenient given the need to coordinate with cluster security policies. For these reasons, most active debugging uses a locally built binary that runs directly on the node, while container based deployments are reserved for integration tests and evaluation runs.

5.1.4 Supporting Tools and Utilities

5.1.4.1 Configuration and local orchestration

A lightweight configuration file `config.yaml` consolidates development toggles that influence local runs and selective deployment. Repository scripts read this file and translate high level options into concrete command line flags and environment variables for the exporter and for auxiliary processes. This keeps day to day operations consistent without editing manifests or code, and aligns with the two workflows in § 5.1.2. Repository scripts map configuration keys to explicit flags for local runs, debug sessions, and ad hoc deploys.

5.1.4.2 Container, cluster, and monitoring utilities

Supporting tools: Docker, kubectl, Helm, k3s, Rancher, Ansible, Prometheus, Grafana. Each is used only where it reduces friction, for example Docker for image builds, kubectl for interaction, and Prometheus/Grafana for observability.

5.1.5 Relevance and Limitations

5.1.5.1 Scope and contribution

The development, build, and debugging environment described in § 5.1.2 and § 5.1.3 is enabling infrastructure rather than a scientific contribution. Its purpose is to make modifications to *Tycho* feasible and to support evaluation, not to advance methodology in software engineering or tooling.

Documenting the environment serves reproducibility and auditability. A reader can verify that results were obtained on bare-metal with access to the required telemetry, and can reconstruct the build pipeline from source to binary and container image. The references to the repository at the start of this section in § 5.1 provide the operational detail that is intentionally omitted from the main text.

5.1.5.2 Boundaries and omissions

Installation steps, editor-specific configuration, system administration, security hardening, and multi tenant policy are out of scope; concrete commands live in the repository. Where concrete commands matter for reproducibility they are available in the repository documentation cited in § 5.1.

5.2 eBPF Collector Integration

5.2.1 Scope and Motivation

The kernel-level eBPF subsystem in Tycho provides the foundation for process-level energy attribution. It captures CPU scheduling, interrupt, and performance-counter events directly inside the Linux kernel, translating them into continuous measurements of CPU ownership and activity. All higher-level aggregation and modeling occur in userspace; this section therefore focuses exclusively on the in-kernel instrumentation and the data it exposes.

Kepler's original eBPF design offered a coarse but functional basis for collecting CPU time and basic performance metrics. Its `sched_switch` tracepoint recorded process runtime, while hardware performance counters supplied instruction and cache data. However, the sampling cadence and aggregation logic were controlled from userspace, producing irregular collection intervals and temporal misalignment with energy readings. Kepler also treated all CPU time as a single undifferentiated category, omitting explicit representation of idle periods, interrupt handling, and kernel threads. As a result, a portion of the processor's activity (often significant under I/O-heavy workloads) remained unaccounted for in energy attribution.

Tycho addresses these limitations through a refined kernel-level design. New tracepoints capture hard and soft interrupts, while extended per-CPU state tracking distinguishes between user processes, kernel threads, and idle execution. Each CPU maintains resettable bins that accumulate idle and interrupt durations within well-defined time windows, providing temporally bounded activity summaries aligned with energy sampling intervals. Cgroup identifiers are refreshed at every scheduling event to maintain accurate container attribution, even when processes migrate between control groups. The result is a stable, low-overhead data source that describes CPU usage continuously and with sufficient granularity to support fine-grained energy partitioning in the subsequent analysis.

5.2.2 Baseline and Architecture Overview

Kepler's kernel instrumentation consisted of a compact set of eBPF programs that sampled process-level CPU activity and a few hardware performance metrics. The core tracepoint, `tp_btf/sched_switch`, captured context switches and estimated per-process runtime by measuring the on-CPU duration between successive events. Complementary probes monitored page cache access and writeback operations, providing coarse indicators of I/O intensity. Hardware performance counters (CPU cycles, instructions, and cache misses) were collected through `perf_event_array` readers, enabling approximate performance characterization at the task level.

While effective for general profiling, this setup lacked the temporal resolution and system coverage required for precise energy correlation. The sampling process was

driven entirely from userspace, leading to irregular collection intervals, and idle or interrupt time was never observed directly. Consequently, CPU utilization appeared complete only from a process perspective, leaving kernel and idle phases invisible to the measurement pipeline.

Tycho extends this architecture into a continuous kernel-side monitoring system. Each CPU maintains an independent state structure recording its current task, timestamp, and execution context. This allows uninterrupted accounting of CPU ownership, even between user-space scheduling events. New tracepoints for hard and soft interrupts measure service durations directly in the kernel, ensuring that all processor activity (user, kernel, or idle) is captured. Dedicated per-CPU bins accumulate these times within fixed analysis windows, which the userspace collector periodically reads and resets. Process-level metrics are stored in an LRU hash map, while hardware performance counters remain integrated via existing PMU readers.

In contrast to Kepler’s snapshot-based sampling, Tycho’s userspace collector consolidates all per-process and per-CPU deltas from the kernel maps once per polling interval into a single tick. This tick-based aggregation provides deterministic timing, reduces memory pressure, and guarantees temporal consistency across heterogeneous metric sources. Data therefore flows linearly from tracepoints to per-CPU maps and onward to the collector, forming a continuous and low-overhead measurement path that supports precise, time-aligned energy attribution.

5.2.3 Kernel Programs and Data Flow

Tycho’s eBPF subsystem consists of a small set of tracepoints and helper maps that together maintain a continuous record of CPU activity. Each program updates per-CPU or per-task data structures in response to kernel events, ensuring that all processor time is accounted for across user, kernel, and idle contexts. The kernel side is event-driven and self-contained; aggregation into time-bounded ticks occurs later in userspace.

Scheduler Switch The central tracepoint, `tp_btf/sched_switch`, triggers whenever the scheduler replaces one task with another. It computes the elapsed on-CPU time of the outgoing process and updates its entry in the `processes` map, which stores cumulative runtime, hardware-counter deltas, and classification metadata such as `cgroup_id`, `is_kthread`, and command name. Hardware counters for instructions, cycles, and cache misses are read from preconfigured PMU readers at this moment, keeping utilization metrics temporally aligned with task execution. Each CPU also maintains a lightweight `cpu_state` structure that records the last timestamp, currently active PID, and task type. When the idle task (PID 0) is scheduled, this structure accumulates idle time locally, allowing continuous accounting even between user-space collection intervals. At polling time, the userspace collector drains these maps atomically, computing per-process deltas since the previous read and bundling all results into a single tick that represents the complete scheduler activity for that interval.

Interrupt Handlers To capture system activity outside user processes, Tycho introduces tracepoints for hard and soft interrupts. Pairs of entry and exit hooks (`irq_handler_entry,exit` and `softirq_entry,exit`) measure the time spent in

each category by recording timestamps in the per-CPU state and adding the resulting deltas to dedicated counters. These durations are aggregated in `cpu_bins`, a resettable per-CPU array that also stores idle time. At each collection cycle, the userspace `bpfCollector` drains and resets these bins, incorporating their totals into the tick structure alongside the per-process deltas. This design maintains continuous coverage of kernel activity while preserving strict temporal alignment between CPU-state transitions and energy sampling.

Page-Cache Probes Kepler’s original page-cache hooks (`fexit/mark_page_accessed` and `tp/writeback_dirty_folio`) are preserved. They increment per-process counters for cache hits and writeback operations, serving as indicators of I/O intensity rather than direct power consumption. These counters are read and reset as part of the same tick aggregation that handles scheduler and interrupt data.

Supporting Maps and Flow All high-frequency updates occur in per-CPU or LRU hash maps to avoid contention. `pid_time_map` tracks start timestamps for active threads, enabling precise runtime computation during context switches. `processes` holds per-task aggregates, while `cpu_states` and `cpu_bins` manage temporal accounting per core. PMU event readers for cycles, instructions, and cache misses remain shared with Kepler’s implementation. At runtime, data flows from tracepoints to these maps and is drained periodically by the userspace collector, which consolidates the deltas into a single per-tick record before storing it in the ring buffer. This batched extraction forms a deterministic, lock-free telemetry path from kernel to analysis, ensuring high-frequency accuracy without per-event synchronization overhead.

5.2.4 Collected Metrics

The kernel eBPF subsystem exports a defined set of metrics describing CPU usage at process and system levels. These values are aggregated in kernel maps and periodically retrieved by the userspace collector for time-aligned energy analysis. Table 5.1 summarizes all metrics grouped by category.

All metrics are aggregated once per polling interval into a single userspace tick that contains per-process and per-CPU deltas. This tick-based representation replaces the former per-sample storage model, ensuring temporal consistency across metrics while retaining the semantics listed above.

Together these metrics form a coherent description of CPU activity. Time-based data quantify ownership of processing resources, hardware counters capture execution intensity, and classification attributes link activity to its origin. This dataset serves as the kernel-level foundation for energy attribution and higher-level modeling in userspace.

5.2.5 Integration with Energy Measurements

The data exported from the kernel define how CPU resources are distributed among processes, kernel threads, interrupts, and idle periods during each observation window. When combined with energy readings obtained over the same interval, these temporal shares provide the basis for proportional energy partitioning. Instead of

Metric	Source hook	Description
<i>Time-based metrics</i>		
Process runtime	<code>tp_btf/sched_switch</code>	Per process. Elapsed on-CPU time accumulated at context switches.
Idle time	Derived from <code>sched_switch</code>	Per node. Aggregated idle time across CPUs.
IRQ time	<code>irq_handler_{entry,exit}</code>	Per node. Aggregated duration spent in hardware interrupt handlers.
SoftIRQ time	<code>softirq_{entry,exit}</code>	Per node. Aggregated duration spent in deferred kernel work.
<i>Hardware-based metrics</i>		
CPU cycles	<code>PMU (perf_event_array)</code>	Per process. Retired CPU cycle count during task execution.
Instructions	<code>PMU (perf_event_array)</code>	Per process. Retired instruction count.
Cache misses	<code>PMU (perf_event_array)</code>	Per process. Last-level cache misses; indicator of memory intensity.
<i>Classification and enrichment metrics</i>		
Cgroup ID	<code>sched_switch</code>	Per process. Control group identifier for container attribution.
Kernel thread flag	<code>sched_switch</code>	Per process. Marks kernel threads executing in system context.
Page cache hits	<code>mark_page_accessed</code>	Per process. Read or write access to cached pages; proxy for I/O activity.
IRQ vectors	<code>softirq_entry</code>	Per process. Frequency of specific soft interrupt vectors.

TABLE 5.1: Metrics collected by the kernel eBPF subsystem.

relying on statistical inference or coarse utilization averages, Tycho attributes energy according to directly measured CPU ownership.

Each collection tick consolidates all per-process runtime and performance-counter deltas together with per-CPU idle and interrupt bins. The sum of these components represents the total active time observed by the processor during that tick, matching the energy sample boundaries defined by the timing engine. This strict temporal alignment ensures that every joule of measured energy can be traced to a specific class of activity—user workload, kernel service, or idle baseline. Through this mechanism, the eBPF subsystem provides the precise temporal structure required for fine-grained, container-level energy attribution in the subsequent analysis stages.

5.2.6 Efficiency and Robustness

The kernel instrumentation is designed to operate continuously with negligible system impact while ensuring correctness across kernel versions. All high-frequency data reside in per-CPU maps, eliminating cross-core contention and locking. Each

processor updates only its local entries in `cpu_states` and `cpu_bins`, while per-task data are stored in a bounded LRU hash that automatically removes inactive entries. Arithmetic within tracepoints is deliberately minimal (timestamp subtraction and counter increments only) so that the added latency per event remains near the measurement noise floor.

Userspace retrieval employs batched `BatchLookupAndDelete` operations, reducing system-call overhead and maintaining constant latency regardless of map size. Hardware counters are accessed through pre-opened `perf_event_array` readers managed by the kernel, avoiding repeated setup costs. Each polling interval consolidates the collected deltas into a single userspace tick, ensuring deterministic timing and consistent aggregation across all CPUs. This architecture allows the subsystem to record thousands of context switches per second while keeping CPU overhead low.

Correctness is maintained through several safeguards. CO-RE (Compile Once, Run Everywhere) field resolution protects the program from kernel-version differences in `task_struct` layouts. Cgroup identifiers are refreshed only for the newly scheduled task, ensuring accurate container labeling even when group membership changes. The idle task (PID 0) and kernel threads are handled explicitly to prevent user-space misattribution, and the resettable bin design enforces strict temporal separation between collection ticks. Together, these measures yield a stable and version-tolerant tracing layer that can run indefinitely without producing inconsistent or overlapping tick data.

5.2.7 Limitations and Future Work

Although the extended eBPF subsystem provides comprehensive temporal coverage of CPU activity, several limitations remain. Its precision is ultimately bounded by the granularity of available energy telemetry, as energy readings must be averaged over fixed collection intervals to remain stable. Within shorter ticks, power fluctuations introduce noise that limits the accuracy of direct attribution.

The current implementation also omits processor C-state and frequency information. While idle and active time are distinguished, variations in power state and dynamic frequency scaling are not yet represented in the collected data. Including tracepoints such as `power:cpu_idle` and `power:cpu_frequency` would enable finer correlation between CPU state transitions and power usage. Additionally, very short-lived processes may terminate and be removed from the LRU map before the next tick is collected, leading to a slight underrepresentation of transient workloads.

5.3 GPU Collector Integration

5.3.1 Introduction and Motivation

Accelerators are increasingly responsible for the energy footprint of modern compute workloads. To attribute this consumption to containerized applications with high temporal accuracy, Tycho must incorporate GPU telemetry into the same unified timing model used for RAPL, eBPF, and Redfish domains (§ 5.7). Achieving this integration is challenging: GPU drivers do not expose continuous measurements but publish telemetry at discrete, hardware-dependent intervals. If these intervals

are not respected, sampling quickly suffers from aliasing, redundant reads, and temporal drift across subsystems, as well as imprecise timing.

NVIDIA’s telemetry interfaces further complicate accurate measurement. The widely used `nvmlDeviceGetPowerUsage` function reports a *one-second trailing average*[57], not the instantaneous power required for sub-second energy attribution. High-frequency power samples are available only through specialised field APIs. Cumulative energy counters (when present) provide authoritative publish boundaries, but they are absent on many devices, including consumer GPUs and MIG configurations. Process-level telemetry is even more restrictive: NVML aggregates utilisation over caller-specified wall-clock windows and provides no information about the device’s internal publish cadence.

Because of these structural limitations, fixed polling intervals or naïve periodic sampling are fundamentally insufficient. Accurate attribution requires that Tycho (i) infer the GPU’s implicit publish cadence, (ii) align its sampling with this cadence, and (iii) integrate both device- and process-level telemetry into the global measurement timeline without violating the strict monotonic ordering enforced by Tycho’s multi-domain ring buffer (§ 5.8.1).

This work introduces two contributions that address these challenges:

- **A phase-aware sampling mechanism** that infers the GPU’s hidden publish rhythm and adaptively concentrates polling around predicted update edges. This transforms GPU sampling from periodic polling into a timing-aligned, event-driven process.
- **A unified integration of GPU telemetry** into Tycho’s global timebase, producing at most one `GpuTick` per confirmed hardware update, with timestamps that are directly comparable to all other energy domains.

Together, these mechanisms provide temporally precise, low-latency GPU measurements while respecting the variability and constraints of NVIDIA’s telemetry ecosystem. This elevates the GPU subsystem to a first-class energy domain in Tycho and enables accurate container-level attribution in heterogeneous accelerator environments.

5.3.2 Architectural Overview

The GPU collector is organised as a layered subsystem that integrates vendor telemetry, adaptive timing, and unified buffering into a coherent measurement pipeline. Its structure reflects Tycho’s core design principles: strict adherence to a monotonic timebase, decoupling of heterogeneous sampling frequencies, and event-driven integration into the platform-wide timing and buffering infrastructure (§ 5.7, § 5.8.1).

At the lowest layer, the collector interfaces with NVIDIA accelerators through a backend abstraction compatible with both NVML and DCGM (“*Data Center GPU Manager*”). This abstraction handles device enumeration, capability probing, MIG topology inspection, and access to device and process telemetry. The collector does not assume uniform backend capabilities: cumulative energy counters, instantaneous power fields, and process-level utilisation may or may not be available depending on hardware generation and configuration.

Above this backend, the collector exposes two measurement paths:

- **Device path.** Retrieves power, utilisation, frequency, thermal, and memory metrics for all devices and MIG instances. These values describe the instantaneous operational state of the accelerator.
- **Process path.** Aggregates per-process utilisation over a backend-defined wall-clock window. This enables multi-tenant attribution but is inherently retrospective and independent of the device’s internal publish cadence.

Both paths feed into a shared sampling layer governed by Tycho’s timing engine. The device path is triggered by a *phase-aware scheduler* that aligns its polling activity with the driver’s implicit publish cadence. The process path is invoked in lock-step with the device polling loop. Process windows advance with each successful query, but only samples associated with confirmed device updates are propagated into `GpuTick` events, which keeps the exported timeline aligned with the device publishes.

The final integration step mirrors all other Tycho subsystems: each confirmed hardware update is converted into a `GpuTick` structure containing device and (optionally) process snapshots, together with a strictly ordered monotonic timestamp. This tick is emitted into Tycho’s multi-domain ring buffer, where it becomes part of the unified energy timeline used for correlation and attribution across eBPF, RAPL, and platform power domains.

Figure 5.1 (later in this section) provides a conceptual overview of this pipeline, illustrating the interaction between the backend interface, the phase-aware sampler, and Tycho’s global collection engine.

5.3.3 Phase-Aware Sampling: Conceptual Overview

GPU drivers publish power and utilisation metrics at discrete, device-internal intervals. These updates occur neither continuously nor synchronously with the sampling frequencies required by Tycho’s timing engine. Because the driver does not expose its publish cadence directly, a naïve fixed-interval polling strategy risks both *aliasing* (missing updates) and *redundancy* (repeatedly reading identical values). Either effect would distort the temporal alignment of GPU measurements with the rest of Tycho’s energy domains.

To avoid this, the GPU collector introduces a *phase-aware sampling* mechanism that infers the driver’s implicit publish cadence from observations. The sampler tracks two quantities: an estimated publish period and the phase offset between the device’s update rhythm and Tycho’s monotonic timebase. By predicting the next likely update moment, the sampler can modulate its polling intensity accordingly:

- **Base mode:** low-frequency polling maintains coarse alignment and detects long-term drift in the publish cadence.
- **Burst mode:** when the current time approaches a predicted update edge, the sampler briefly increases its polling frequency to minimise the latency between the hardware update and Tycho’s observation of it.

This adaptive strategy ensures that Tycho reads the device only when a fresh publish is likely to be available. Freshness is determined by comparing each snapshot to the most recent confirmed update, preferably via cumulative energy counters when present, or otherwise via power deltas exceeding a configurable threshold. Only when a new publish is detected does the sampler emit an event.

The resulting behaviour is simple but powerful:

*Each hardware update produces at most one *GpuTick*, and no tick is emitted unless the device has genuinely updated.*

This one-to-one correspondence is critical for integrating GPU measurements into Tycho’s unified energy timeline. It guarantees temporal fidelity, eliminates redundant samples, and ensures that GPU metrics are directly comparable with other measurements obtained under the same timing and buffering semantics.

The next subsection formalises this behaviour by presenting the timing model used to estimate publish periods, track phase offsets, and define the burst window around predicted update edges.

5.3.4 Phase-Aware Timing Model

The timing model enables Tycho to infer the GPU driver’s implicit publish cadence and to align sampling with the actual update moments of the hardware. It maintains two quantities derived from confirmed device updates: an estimate of the *publish period* and a *phase offset* relative to Tycho’s monotonic clock. This subsection presents the model in a unified mathematical form.

Let $t_{\text{obs},k}$ denote the monotonic timestamp of the k -th confirmed hardware update. From these observations, the sampler derives the period estimate \hat{T}_k and phase estimate $\hat{\phi}_k$.

Period Estimation. Each new inter-update interval

$$\Delta t_k = t_{\text{obs},k} - t_{\text{obs},k-1}$$

provides a direct sample of the device’s publish period. To remain robust to jitter caused by DVFS, thermal transitions, or backend noise, the sampler applies an exponential moving average (EMA):

$$\hat{T}_k = (1 - \alpha_T) \hat{T}_{k-1} + \alpha_T \Delta t_k,$$

with $\alpha_T \in (0, 1)$ controlling the smoothing strength. The resulting estimate is clamped to a stable range derived from Tycho’s engine cadence, ensuring predictable behaviour across different GPUs.

Phase Tracking. Given a current period estimate, the expected time of the k -th update is

$$\hat{t}_k = t_{\text{obs},k-1} + \hat{\phi}_{k-1} + \hat{T}_k.$$

The deviation

$$\delta_k = t_{\text{obs},k} - \hat{t}_k$$

represents the phase error. The sampler updates its phase estimate through a second EMA:

$$\hat{\phi}_k = (\hat{\phi}_{k-1} + \alpha_\phi \delta_k) \bmod \hat{T}_k,$$

where α_ϕ is a small adaptation constant. This ensures smooth convergence toward the device's true publish rhythm.

Edge Prediction. At an arbitrary time t_{now} , the predicted next update edge is

$$t_{\text{next}} = t_{\text{obs},k} + n \cdot \hat{T}_{k+1} + \hat{\phi}_{k+1},$$

where n is the smallest non-negative integer such that $t_{\text{next}} \geq t_{\text{now}}$. This prediction determines where sampling effort should be concentrated.

Burst Window. To avoid continuous high-frequency polling, the sampler restricts hyperpolling to a narrow window of half-width w around t_{next} :

$$\text{mode}(t_{\text{now}}) = \begin{cases} \text{burst}, & |t_{\text{now}} - t_{\text{next}}| \leq w, \\ \text{base}, & \text{otherwise.} \end{cases}$$

The width w is expressed as a fraction of the calibrated engine cadence, ensuring proportional behaviour across platforms.

Summary. The phase-aware model enables Tycho to infer the GPU's implicit publish cadence solely from observed updates and to align sampling with the device's true update edges. By combining smooth period estimation, adaptive phase correction, and narrow burst windows around predicted publishes, the sampler detects new hardware updates with low latency and emits at most one GpuTick per publish.

Figure 5.1 visualises the behaviour of the phase-aware sampling model introduced above. The top lane represents the hardware's implicit publish sequence; the middle lane shows Tycho's adaptive polling pattern during both calibration and the phase-locked regime; and the bottom lane shows the resulting GPU ticks, demonstrating the one-to-one mapping between fresh device updates and emitted GpuTick events.

FIGURE 5.1: Phase-aware GPU polling timeline

5.3.5 Event Lifecycle

The GPU collector converts each confirmed hardware update into a monotonically-timestamped `GpuTick` that integrates into Tycho’s multi-domain energy timeline. The lifecycle consists of five stages: polling, device acquisition, optional process acquisition, freshness detection, and tick emission.

1. Poll Initiation. Polling is triggered solely by the phase-aware scheduler (§ 5.3.3, § 5.3.4). Base-mode polls track long-term cadence drift; burst-mode polls densely probe the vicinity of predicted update edges. Each poll receives a monotonic timestamp t_{now} that anchors the resulting event.

2. Device Snapshot Acquisition. A poll retrieves device-level telemetry for all GPUs and MIG instances, capturing power, utilisation, clocks, thermals, and memory state. All values reflect the device’s instantaneous condition at t_{now} and form a consistent cross-device snapshot of the accelerator subsystem.

3. Optional Process Snapshot Acquisition. If available, process-level telemetry is sampled over a backend-defined wall-clock window (§ 5.3.6). Although retrospective, these samples are associated with the same monotonic timestamp as the device snapshot, ensuring that device and process data remain correlated without temporal ambiguity.

4. Freshness Determination. The collector compares the new device snapshot with the most recent confirmed update. Cumulative energy counters, when available, serve as the authoritative freshness signal; otherwise Tycho uses a power-delta threshold to avoid counting noise as updates. Only fresh snapshots update the period and phase estimators and proceed to the next stage.

5. Tick Emission. A fresh observation is converted into a `GpuTick` containing device and (optional) process snapshots and the timestamp t_{now} . The tick is then delivered to Tycho’s multi-domain ring buffer (§ 5.8.1). If no fresh update is detected, the poll produces no tick, ensuring that the GPU timeline faithfully reflects the hardware’s publish cadence.

Summary. The event lifecycle ensures that GPU telemetry is sampled only when meaningful, timestamped consistently with Tycho’s timebase, and integrated without blocking or duplication. Each hardware update generates at most one `GpuTick`, providing a precise, causally ordered input to Tycho’s cross-domain energy attribution pipeline.

5.3.6 Per-Process Telemetry Window

Device-level metrics describe the instantaneous state of each GPU, but many applications require attributing accelerator activity to individual processes or containers. NVIDIA’s interfaces provide such information only in the form of *aggregated utilisation over a caller-specified time window*. Correctly selecting and interpreting this window is essential for obtaining meaningful per-process data and for aligning process-level records with the device-level timeline maintained by Tycho.

Wall-Clock Semantics. Unlike device publishes, which occur on the GPU’s internal cadence, NVIDIA’s per-process APIs integrate utilisation over a duration supplied by the caller. These interfaces expect a *wall-clock* interval, expressed in milliseconds, rather than a duration derived from Tycho’s monotonic timebase. The distinction is crucial: Tycho’s monotonic clock operates on an internal quantum chosen to support high-resolution scheduling (§ 5.7), but this quantum has no defined relationship to real elapsed time. Using monotonic differences directly would produce windows that are several orders of magnitude too short, yielding incomplete utilisation samples.

For this reason, Tycho maintains a separate wall-clock origin for each GPU or MIG instance. Whenever process telemetry is requested, the duration since the last successful query is computed using wall-clock time, ensuring that the backend receives a true real-time interval.

Window Derivation. For each owner (physical GPU or MIG instance), Tycho records the timestamp $t_{\text{last}}^{(i)}$ of the most recent successful process query. When a new query occurs at time $t_{\text{now}}^{(i)}$, the raw duration

$$\Delta t_{\text{raw}}^{(i)} = t_{\text{now}}^{(i)} - t_{\text{last}}^{(i)}$$

is transformed according to backend expectations:

1. *Clamping*. The duration is restricted to a safe range $\Delta t_{\min} \leq \Delta t^{(i)} \leq \Delta t_{\max}$ to avoid zero-length or excessively long sampling windows.
2. *Millisecond granularity*. NVIDIA’s process APIs accept durations in whole milliseconds. Tycho therefore rounds the clamped value up to the next full millisecond to prevent systematic underestimation of utilisation.

After a successful query, the wall-clock origin is updated to $t_{\text{last}}^{(i)} \leftarrow t_{\text{now}}^{(i)}$, establishing continuity across successive sampling windows.

Temporal Alignment with Device Updates. Even though per-process telemetry describes accumulated activity rather than a snapshot, Tycho ensures that all process samples remain aligned with the device timeline. Each process record is associated with the device-level timestamp of the poll that triggered the query. If a device has never produced a fresh update, the collector uses the timestamp of the most recent device tick as the initial origin for its process window. This guarantees that device and process metrics are linked to the same global temporal reference and can be fused without interpolation.

Backend Variability and Robustness. Process-level support varies widely across NVIDIA hardware and software stacks. DCGM-capable systems typically expose high-quality, high-resolution utilisation data, whereas NVML-only systems (particularly consumer GPUs) may provide limited or noisy information. Tycho’s design accommodates these differences gracefully: when a process query fails, the wall-clock origin is still advanced to prevent tight retry loops, and device-level sampling proceeds unaffected. This ensures stable behaviour even in mixed configurations where only a subset of devices expose meaningful per-process telemetry.

Summary. By separating wall-clock process windows from monotonic device timestamps and carefully aligning both within Tycho’s timing architecture, the GPU collector provides process-level telemetry that is semantically correct, temporally consistent, and robust to backend limitations. This separation of concerns is essential for accurate multi-tenant attribution in heterogeneous accelerator environments.

5.3.7 Collected Metrics

The GPU collector reports two complementary categories of telemetry that together describe both the instantaneous state of each accelerator and the distribution of GPU activity across processes. All metrics are incorporated into a unified `GpuTick` structure and timestamped under Tycho’s monotonic timebase, ensuring direct comparability with other domains.

Device-Level Metrics. Device and MIG-level metrics capture the operational state of the accelerator at the moment Tycho detects a fresh hardware update. These values include power, utilisation, memory usage, thermal data, and clock frequencies, along with backend-specific fields such as instantaneous power samples or cumulative energy counters. Cumulative energy, when available, is used as the authoritative indicator of publish boundaries and therefore plays a central role in the timing model and freshness detection. Due to a tendency of NVIDIA GPUs to still produce (invalid) values when queried for cumulative energy, the actual availability of correct cumulative energy-metrics is verified during the initial calibration. The collector uses a per-device validity mask derived from this calibration when performing freshness detection: cumulative energy is treated as authoritative only for devices whose counters are verified as monotonic, and other devices fall back to a power-delta threshold.

Process-Level Metrics. Process-level metrics describe the aggregated utilisation of individual processes over the backend-defined wall-clock window (§ 5.3.6). They enable multi-tenant attribution by associating GPU activity with specific applications, containers, or pods. Because these values represent accumulated work rather than an instantaneous snapshot, they are paired with the device-level timestamp of the triggering poll, ensuring temporal consistency within Tycho’s unified timeline.

Tables 5.2 and 5.3 summarise the metrics collected at both levels.

Metric	Unit	Description
<i>Utilisation metrics</i>		
SMUtilPct	%	Streaming multiprocessor (SM) utilisation.
MemUtilPct	%	Memory controller utilisation.
EncUtilPct	%	Hardware video encoder utilisation.
DecUtilPct	%	Hardware video decoder utilisation.
<i>Energy and thermal metrics</i>		
PowerMilliW	mW	Instantaneous power via NVML/DCGM (1s average).
InstantPowerMilliW	mW	High-frequency instantaneous power from NVIDIA field APIs.
CumEnergyMilliJ	mJ	Cumulative energy counter (preferred freshness signal).
TempC	°C	GPU temperature.
<i>Memory and frequency metrics</i>		
MemUsedBytes	bytes	Allocated framebuffer memory.
MemTotalBytes	bytes	Total framebuffer memory.
SMClockMHz	MHz	SM clock frequency.
MemClockMHz	MHz	Memory clock frequency.
<i>Topology and metadata</i>		
DeviceIndex	-	Numeric device identifier.
UUID	-	Stable device UUID.
PCIBusID	-	PCI bus identifier.
IsMIG	-	Indicates a MIG instance.
MIGParentID	-	Parent device index for MIG instances.
Backend	-	Backend type (NVML or DCGM).

TABLE 5.2: Device- and MIG-level metrics collected by the GPU subsystem.

Metric	Unit	Description
Pid	-	Process identifier.
ComputeUtil	%	Per-process SM utilisation aggregated over the query window.
MemUtil	%	Per-process memory controller utilisation.
EncUtil	%	Per-process encoder utilisation.
DecUtil	%	Per-process decoder utilisation.
GpuIndex	-	Device or MIG instance to which the sample belongs.
GpuUUID	-	Corresponding device UUID.
TimeStampUS	µs	Backend timestamp associated with the utilisation record.
<i>MIG metadata (when applicable)</i>		
GpuInstanceID	-	MIG GPU instance identifier.
ComputeInstanceID	-	MIG compute-instance identifier.

TABLE 5.3: Process-level metrics collected over a backend-defined time window.

5.3.8 Configuration Parameters

The GPU collector exposes only a minimal set of configuration parameters. In contrast to traditional monitoring systems that require hand-tuned polling intervals, Tycho derives the parameters of the phase-aware sampler directly from the engine

cadence calibrated during system startup (§ 5.7). This ensures that GPU sampling inherits the same temporal consistency as all other energy domains and remains robust across heterogeneous hardware.

The configuration governs three tightly coupled aspects of the sampling mechanism:

- **Cadence bounds.** The initial estimate of the GPU publish period, as well as its minimum and maximum permissible values, are expressed as simple fractions of the engine cadence. This constrains the period estimator to a stable range without relying on device-specific heuristics.
- **Polling intervals.** Both base-mode and burst-mode polling frequencies are derived from fixed ratios of the engine cadence. As a result, Tycho polls aggressively only when a publish is predicted without requiring manual tuning.
- **Burst-window width.** The half-width of the burst window around t_{next} is likewise tied to the engine cadence. This determines how narrowly the sampler focuses its hyperpolling effort around predicted publish edges.

Because all parameters scale with the calibrated cadence, the sampler adapts automatically to different GPU generations, backend behaviours, and platform timing characteristics. No user-facing configuration is required; temporal correctness follows directly from Tycho’s system-wide timing model.

5.3.9 Robustness and Limitations

The GPU collector is designed to operate reliably across heterogeneous hardware, backend capabilities, and driver behaviours. Its phase-aware sampling, decoupled event queue, and unified timebase ensure that GPU telemetry integrates cleanly with Tycho’s multi-domain measurement framework. Nevertheless, several structural constraints in NVIDIA’s telemetry ecosystem define the practical limits of what can be inferred and with what temporal precision.

Backend Variability. The capabilities of NVML and DCGM differ significantly across GPU generations and product classes. Datacenter GPUs typically expose cumulative energy counters, high-frequency instant power fields, and stable process-level utilisation, while consumer GPUs often lack cumulative energy and provide only coarse utilisation metrics. Tycho handles these differences gracefully (sampling continues even when certain fields are missing) but the quality of the resulting attribution reflects the capabilities of the underlying hardware.

Power Measurement Limitations. The widely used `nvmlDeviceGetPowerUsage` call provides a *one-second trailing average*, which is unsuitable as a high-frequency power signal. Tycho therefore relies on instantaneous power fields (e.g. field 186) when available, and uses cumulative energy counters as the authoritative freshness indicator. On devices lacking both instantaneous fields and cumulative energy, power-based freshness detection becomes less precise, increasing uncertainty in the inferred publish cadence.

Process Attribution Constraints. Process-level utilisation is inherently aggregated over a wall-clock window, since NVIDIA provides no access to per-process instantaneous state. This retrospective design imposes two limitations: (i) spikes shorter than the sampling window may be attenuated, and (ii) per-process values cannot be aligned to the exact moment of a device publish. Tycho addresses this by using the device-level timestamp to anchor all process records, but the granularity of attribution ultimately depends on backend resolution.

Cadence Inference and Jitter. Because the driver does not expose its publish cadence, Tycho must infer it indirectly. Under conditions of high load, thermal transitions, or DVFS-induced jitter, publish intervals may vary, introducing uncertainty into edge prediction. Tycho’s EMA-based estimators maintain stability under such variability, but prediction accuracy is inherently bounded by the noisiness of the underlying telemetry.

Mixed and MIG Configurations. Systems combining MIG and non-MIG devices, or devices with partial telemetry support, may expose inconsistent field availability across accelerators. Cumulative energy counters may exist for some instances but not others; process information may be available only at the parent-device level. Tycho handles these cases through per-device fallbacks and independent cadence models, but the precision of multi-GPU attribution varies with the fidelity of each device’s telemetry.

Vendor support scope. The current GPU collector supports only NVIDIA-based accelerators, following the design of Kepler. While this excludes other vendors, it is justifiable: according to market research[58], NVIDIA captured approximately 93% of the server GPU revenue in 2024. Given this dominant share, focusing on NVIDIA hardware is acceptable for the majority of data-centre GPU deployments.

5.4 RAPL Collector Integration

5.4.1 Scope and Baseline

RAPL-based telemetry provides CPU energy readings at the level of logical power domains such as package, cores, uncore, and DRAM. Tycho reuses Kepler’s existing RAPL implementation almost unchanged: discovery, scaling, and raw counter reads are still provided by the shared `components` package (via the `power-interface`), which wraps the kernel’s `powercap` interface and related mechanisms. This collector therefore does not introduce a new hardware access path but instead focuses on integrating the existing RAPL metrics into Tycho’s timing and buffering model.

5.4.2 Architecture and Data Flow

The collector is deliberately simple and stateless. On each engine tick, the `Collect` function:

1. Verifies that system-wide RAPL collection is supported via `components.IsSystemCollectionSupported()`.
2. Obtains a snapshot of cumulative energy counters for all sockets and domains through `components.GetAbsEnergyFromNodeComponents()`.

3. Translates the per-socket results into a `RaplTick` structure containing:
 - a monotonic timestamp derived from `clock.Mono`, and
 - a map from socket identifier to domain counters.
4. Pushes exactly one immutable `RaplTick` into the shared ring buffer.

The tick stores raw, monotonically increasing counters in millijoules rather than precomputed deltas. Downstream analysis components compute inter-tick differences, perform wraparound handling, and align RAPL energy with CPU activity and platform-level power traces. This separation keeps the collector minimal while allowing the analysis layer to apply a consistent attribution strategy across all energy domains.

5.4.3 Collected Metrics

Table 5.4 summarises the metrics stored in each `RaplTick`. All counters are subject to platform availability.

Metric	Unit	Description
<i>Per-socket energy counters</i>		
Pkg	mJ	Cumulative package energy per socket (RAPL PKG domain).
Core	mJ	Cumulative core energy per socket (RAPL PP0 domain), when available.
Uncore	mJ	Cumulative uncore energy per socket (RAPL PP1 or uncore domain), when available.
DRAM	mJ	Cumulative DRAM energy per socket (RAPL DRAM domain), if the platform exposes it.
<i>Metadata</i>		
Source	–	Identifier of the active RAPL backend (for example <code>powercap</code>)
Sockets	–	Map from socket identifier to the corresponding set of domain counters.
SampleMeta.Mono	–	Monotonic timestamp assigned by Tycho's timing engine at the moment of collection.

TABLE 5.4: Metrics exported by the RAPL collector per `RaplTick`.

These metrics provide a compact, hardware-backed view of CPU and memory-subsystem energy at socket granularity. Combined with the timing guarantees of Tycho's engine and ring buffer, they form the CPU-related energy baseline against which per-process activity and platform-level power are later correlated.

5.4.4 Limitations and Reuse

Because RAPL domain availability is hardware dependent, not all fields in Table 5.4 are present on every platform. Some systems expose only package-level counters, while others additionally provide core, uncore, or DRAM domains. The collector reports only what the hardware exposes and does not attempt to approximate or reconstruct missing values.

Beyond this domain variability, no further limitations apply. The collector is intentionally minimal and serves as a timing-aware wrapper around the raw counters, providing reliable cumulative energy readings without adding intermediate modelling or transformation.

5.5 Redfish Collector Integration

The Redfish collector retrieves node-level power measurements from the server’s Baseboard Management Controller (BMC) through the Redfish API. As an out-of-band source, it complements in-band telemetry such as RAPL by providing a hardware-validated view of total chassis power. Tycho integrates these measurements into its global timing framework, ensuring that BMC-sourced data can be correlated with all other collectors using a common monotonic clock.

5.5.1 Overview and Objectives

Redfish power readings are updated asynchronously and often with vendor-specific timing behaviour. Tycho therefore focuses on robustness, controlled polling, and precise timestamping rather than high-frequency sampling. The collector executes a single BMC query at the global engine cadence, extracts the current chassis power value, and emits a sample only when necessary. All readings are timestamped with Tycho’s monotonic timebase and annotated with freshness metadata to express their temporal accuracy.

5.5.2 Baseline in Kepler

Kepler’s original Redfish integration consisted of a periodic background ticker that queried the BMC at fixed intervals, typically every sixty seconds. It retrieved only instantaneous chassis power and made no distinction between new and repeated measurements. No mechanism existed to detect stale data, associate readings with BMC timestamps, or align Redfish values with other collectors. The Redfish implementation was therefore sufficient for coarse system-power reporting, but not suitable for the finer temporal structure required by Tycho.

5.5.3 Refactoring and Tycho Extensions

5.5.3.1 Timing Ownership and Polling Control

Tycho removes Kepler’s internal Redfish ticker entirely. Polling is performed exclusively by Tycho’s global timing engine, which invokes the collector once per engine tick. This ensures that all Redfish interactions occur in lockstep with the rest of the measurement pipeline and that every sample can be aligned unambiguously with simultaneous energy and utilization values from other collectors.

The polling frequency itself is never altered by the Redfish collector. Tycho maintains deterministic, externally selected polling intervals regardless of BMC behaviour.

5.5.3.2 Sequence-Based Newness Detection

Many BMCs return identical payloads for extended periods and only publish new power values intermittently. To avoid emitting redundant samples, Tycho uses a per-chassis sequence number provided by the Redfish client. Each measurement is

considered fresh only when this sequence number differs from the one observed in the previous engine tick.

No header-based (for example ETag) or value-delta heuristics are used. Newness is driven solely by this explicit sequence value, ensuring a consistent and vendor-agnostic update mechanism.

5.5.3.3 Heartbeat Mechanism and Freshness Metric

Because BMC refresh cycles can be irregular, Tycho maintains a heartbeat window for each chassis. If no new Redfish sample has appeared within this window, the collector emits a heartbeat sample that carries forward the last known power value. This prevents gaps in the power time series while avoiding unnecessary fabrication of data.

Each emitted sample includes a freshness metric, defined as the time difference between the BMC-reported timestamp (when available) and the local collection time. This value quantifies the latency of the underlying Redfish pipeline. Freshness does not influence newness detection; it is an informational quality indicator for the analysis layer.

5.5.3.4 Fixed vs Auto Heartbeat Mode

Tycho supports two Redfish operating modes, selected by `TYCHO_REDIFSH_POLL_AUTOTUNE`. Both modes perform BMC polling strictly at the global engine cadence.

In fixed mode, the heartbeat window is defined entirely by the user through `TYCHO_REDIFSH_HEARTBEAT_MS`. This guarantees deterministic behaviour and is appropriate for reproducible benchmarks.

In auto mode, Tycho adapts the heartbeat window to the BMC's observed update pattern. Whenever a fresh sequence number is detected, the collector measures the inter-arrival duration to the previous update and stores it in a sliding window. The median of this window is taken as the representative publication period, and the heartbeat timeout is set to approximately 1.5 times this value, clamped between conservative bounds. This technique aligns Tycho's emission behaviour with the hardware's natural update rhythm while retaining deterministic polling.

5.5.4 Collected Metrics

The Redfish collector emits one record per chassis whenever a new measurement is detected or a heartbeat event occurs. Each record is timestamped using Tycho's monotonic clock and annotated with metadata relevant for temporal correlation. Table 5.5 summarises the collected fields.

Energy values such as `EnergyMilliJ` are computed downstream by integrating the power series and are not directly produced by the collector.

5.5.5 Integration and Data Flow

The Redfish collector is a passive component within Tycho's unified collection pipeline. At each engine tick it performs one BMC query, evaluates newness and heartbeat conditions, attaches monotonic timestamps, and writes the resulting record into a

Metric	Unit	Description
<i>Primary power metric</i>		
PowerWatts	W	Instantaneous chassis power reported by the BMC.
<i>Temporal and identity metadata</i>		
ChassisID	-	Identifier of the chassis or enclosure.
Seq	-	Server-provided sequence number indicating new measurements.
SourceTime	s	Timestamp provided by the BMC, if available.
CollectorTime	s	Local collection time of the measurement.
FreshnessMs	ms	Difference between SourceTime and CollectorTime.

TABLE 5.5: Metrics collected by the Redfish collector.

synchronized ring buffer. No additional processing occurs within the collector; all energy computations and correlations across metrics are performed in Tycho’s analysis stage.

5.5.6 Accuracy and Robustness Improvements

Tycho improves Redfish robustness by combining explicit sequence-based newness tracking, adaptive heartbeat windows, and freshness estimation. Sequence tracking ensures that repeated BMC responses do not produce redundant samples. Adaptive heartbeat windows accommodate BMCs with slow or irregular update cycles. Freshness metadata exposes the latency of Redfish timestamps, allowing the analysis layer to assess the temporal reliability of each reading.

These measures provide stable and chronologically consistent power telemetry across heterogeneous BMC implementations.

5.5.7 Limitations

Redfish sampling remains limited by the update rate and timestamp quality of the underlying BMC. Most implementations refresh power data at intervals on the order of one to two seconds. Redfish does not report component-level power breakdowns; only total chassis power is available. For fine-grained attribution, Tycho relies on complementary in-band collectors such as RAPL and eBPF.

5.6 Configuration Management

5.6.1 Overview and Role in the Architecture

Tycho adopts a simple, centralized configuration layer that is initialized during exporter startup and made globally accessible through typed structures. This layer defines all runtime parameters controlling timing, collection, and analysis behaviour. It serves as the interface between user-defined settings and the internal scheduling and buffering logic described in § 5.7.

The configuration is loaded once at startup, combining defaults, environment variables, and optional overrides passed through Helm or local flags. Its purpose is

not to support dynamic reconfiguration, but to provide deterministic, reproducible operation across (experimental) runs. No backward compatibility with previous Kepler versions is maintained.

5.6.2 Configuration Sources

Configuration values can be provided in three ways: first, through a `values.yml` file during Helm installation, second, as command-line flags for local or debugging builds, and third, via predefined environment variables that act as defaults.

During startup, Tycho sequentially evaluates these sources in fixed order—defaults are loaded first, then environment variables, followed by any user-supplied overrides. The resulting configuration is stored in memory and printed once for verification. After initialization, all components reference the same in-memory configuration, ensuring consistent behaviour across collectors and analysis modules.

5.6.3 Implementation and Environment Variables

The configuration implementation in Tycho closely follows the approach used in Kepler v0.9.0. Each configuration key is mapped to an environment variable, which is resolved at startup through dedicated lookup functions. If no variable is set, the corresponding default value is applied. This mechanism enables flexible configuration without external dependencies or complex parsing logic. All variables are read once during initialization, after which they are cached in typed configuration structures. This guarantees consistent operation even if environment variables change later, since Tycho is not designed for live reconfiguration. The configuration layer is invoked before the collectors and timing engine are instantiated, ensuring that parameters such as polling intervals, buffer sizes, or analysis triggers are available to all components from the first cycle onward.

5.6.3.1 Validation and Normalization at Startup

During initialization, Tycho validates all user inputs and normalizes them to a consistent, safe configuration. First, basic bounds are enforced: the global timebase quantum must be positive, non-negative values are required for all periods and delays, and missing essentials fall back to minimal defaults. Trigger coherence is then checked. If `redfish` is selected while the Redfish collector is disabled, Tycho switches to the timer trigger and ensures a valid interval. Unknown triggers default to `timer`.

All periods and delays are aligned to the global quantum so that scheduling, buffering, and analysis operate on a common time grid. The analysis wait `DelayAfterMs` is raised if needed to cover the longest enabled per-source delay. Buffer sizing is derived from the slowest effective acquisition path (poll period plus delay) and the analysis wait, with a small safety margin. If Redfish is enabled, its heartbeat requirement is included to guarantee coverage. Sanity checks also ensure plausible Redfish cadence and warn if no collectors are enabled. Non-fatal environment hints (for example the RAPL powercap path) are reported at low verbosity.

The result is a single, internally consistent configuration snapshot. Adjustments are announced once at startup to aid reproducibility while avoiding log noise.

5.6.4 Evolution in Newer Kepler Versions

Subsequent Kepler releases (v0.10.0 and later) have replaced the environment-variable system with a unified configuration interface based on CLI flags and YAML files. This modernized approach simplifies configuration management and aligns better with Kubernetes conventions, providing clearer defaults and validation at startup.

Tycho intentionally retains the v0.9.0 model to maintain structural continuity with its experimental foundation. Since configuration handling is not a research focus, adopting the newer scheme would add complexity without scientific benefit. Nevertheless, the newer Kepler design confirms that Tycho's configuration logic can be migrated with minimal effort if long-term maintainability becomes a requirement.

5.6.5 Available Parameters

All parameters are read at startup and remain constant throughout execution. The following table 5.6 summarizes the user-facing configuration variables with their default values and functional scope. Internal or experimental parameters are omitted for clarity.

XX
 CHECK THIS TABLE BEFORE HANDIN, THIS NEEDS CLEANUP
 XXX

Variable	Default	Description
<i>Collector enable flags</i>		
TYCHO_COLLECTOR_ENABLE_BPF	true	Enables eBPF-based process metric collection.
TYCHO_COLLECTOR_ENABLE_RAPL	true	Enables RAPL energy counter collection.
TYCHO_COLLECTOR_ENABLE_GPU	true	Enables GPU power telemetry collection.
TYCHO_COLLECTOR_ENABLE_REDISH	true	Enables Redfish-based BMC power collection.
<i>Timing and delays</i>		
TYCHO_TIMEBASE_QUANTUM_MS	1	Base system quantum (ms) defining the global monotonic time grid.
TYCHO_RAPL_POLL_MS	50	RAPL polling interval (ms).
TYCHO_GPU_POLL_MS	200	GPU telemetry polling interval (ms).
TYCHO_REDISH_POLL_MS	1000	Redfish polling interval (ms); should be below BMC publish cadence.
TYCHO_RAPL_DELAY_MS	0	Expected delay between workload change and RAPL visibility (ms).
TYCHO_GPU_DELAY_MS	200	Expected delay between workload change and GPU visibility (ms).
TYCHO_REDISH_DELAY_MS	0	Expected delay between workload change and Redfish visibility (ms).
TYCHO_REDISH_HEARTBEAT_MAX_GAP_MS	3000	Maximum tolerated gap between consecutive Redfish samples (ms).
<i>Autotuning controls</i>		
TYCHO_RAPL_POLL_AUTOTUNE	true	Enables automatic calibration of RAPL polling interval.
TYCHO_RAPL_DELAY_AUTOTUNE	true	Enables automatic calibration of RAPL delay.
TYCHO_GPU_POLL_AUTOTUNE	true	Enables automatic calibration of GPU polling interval.
TYCHO_GPU_DELAY_AUTOTUNE	true	Enables automatic calibration of GPU delay.
TYCHO_REDISH_POLL_AUTOTUNE	true	Enables automatic calibration of Redfish polling interval.
TYCHO_REDISH_DELAY_AUTOTUNE	true	Enables automatic calibration of Redfish delay.
<i>Analysis parameters</i>		
TYCHO_ANALYSIS_TRIGGER	"timer"	Defines analysis trigger: <code>redfish</code> or <code>timer</code> .
TYCHO_ANALYSIS_EVERY_SEC	15	Interval for timer-based analysis (s).
TYCHO_ANALYSIS_DETECT_LONGEST_DELAY	false	Enables detection of the longest observed metric delay.

TABLE 5.6: User-facing configuration variables available in Tycho.

In summary, Tycho's configuration layer provides a single, immutable snapshot of all timing, polling, and analysis parameters. It is loaded once at startup, validated, normalized to a shared timebase, and propagated to all collectors and analysis modules. The design prioritizes reproducibility and correctness: no live reconfiguration is supported, and all behaviour is derived from explicit user input or well-defined defaults. This central configuration snapshot ensures that the timing engine, collectors, and buffering subsystem operate in a coherent, predictable manner throughout the entire runtime.

5.7 Timing Engine

5.7.1 Overview and Motivation

Tycho introduces a dedicated timing engine that replaces the synchronous update loop used in Kepler with an event-driven, per-metric scheduling layer. While the conceptual motivation for this change was discussed in § ??, its practical purpose is straightforward: to decouple the collection frequencies of heterogeneous telemetry sources and to establish a common temporal reference for subsequent analysis.

Each collector in Tycho (e.g., RAPL, eBPF, GPU, Redfish) operates under its own polling interval and is triggered by an aligned ticker maintained by the timing engine. All tickers share a single epoch (base timestamp) and are aligned to a configurable time quantum, ensuring deterministic phase relationships and bounded drift across all metrics. This architecture allows high-frequency sources to capture fine-grained temporal variation while preserving coherence with slower metrics.

The timing engine thus provides the temporal backbone of Tycho: it defines *when* each collector produces samples and ensures that all samples can later be correlated on a unified, monotonic timeline. Collected samples are pushed immediately into per-metric ring buffers, described in § 5.8, which retain recent histories for downstream integration and attribution.

5.7.2 Architecture and Design

The timing engine is implemented in the `engine.Manager` module. It acts as a lightweight scheduler that governs the execution of all metric collectors through independent, phase-aligned tickers. During initialization, each collector registers its callback function, polling interval, and enable flag with the manager. Once started, the manager creates one aligned ticker per enabled registration and launches each collector in a dedicated goroutine. All tickers share a single epoch, captured at startup, to guarantee deterministic alignment across collectors.

This design contrasts sharply with the global ticker used in Kepler, where a single update loop refreshed all metrics at a fixed interval. In Tycho, each ticker operates at its own cadence, determined by the configured polling period of the respective collector. For instance, RAPL may poll every 50 ms, GPU metrics every 200 ms, and Redfish telemetry every second, yet all remain phase-aligned through the shared epoch.

To maintain temporal consistency, the timing engine relies on the `clock` package, which defines both the aligned ticker and a monotonic timeline abstraction. The aligned ticker computes the initial delay to the next multiple of the polling period and then emits ticks at strictly periodic intervals. Each emitted epoch is converted into Tycho's internal time representation using the `Mono` clock, which maps wall-clock time to discrete quantum indices. The quantum defines the global temporal resolution (default: 1 ms) and guarantees strictly non-decreasing tick values, even under concurrency or system jitter.

The engine imposes minimal constraints on collector behavior: callbacks are expected to perform non-blocking work, typically pushing samples into the respective ring buffer, and to return immediately. This ensures low scheduling jitter and

prevents slow collectors from influencing others. Lifecycle control is context-driven: when the execution context is cancelled, all ticker goroutines stop gracefully, and the manager waits for their completion before shutdown.

5.7.3 Synchronization and Collector Integration

All collectors in Tycho are synchronized through a shared temporal reference established at engine startup. The `Manager` captures a single epoch and provides it to every aligned ticker, ensuring that all collectors operate on the same epoch even if their polling intervals differ by several orders of magnitude. As a result, each collector's tick sequence can be expressed as a deterministic multiple of the global epoch, allowing later correlation between independently sampled metrics without interpolation artefacts.

Collectors register themselves before the timing engine is started. Each registration includes the collector's name, polling period, enable flag, and a `collect()` callback that executes whenever the corresponding ticker emits a tick. This callback receives both the current execution context and the aligned epoch, which is immediately converted into Tycho's internal monotonic time representation via the `Mono.From()` function. The collector then packages its raw measurements into a typed sample and pushes it to its corresponding ring buffer.

Because all collectors share the same monotonic clock and quantization step, the resulting sample streams can be merged and compared without further time normalization. Fast sources, such as RAPL or eBPF, provide dense sequences of measurements at fine granularity, while slower sources such as Redfish or GPU telemetry produce sparser but phase-aligned data points. This synchronization model eliminates the implicit coupling between sources that existed in Kepler and replaces it with a deterministic, time-driven coordination layer suitable for high-frequency, heterogeneous metrics.

5.7.4 Lifecycle and Configuration

The timing engine is initialized during Tycho's startup phase, after the metric collectors and buffer managers have been constructed. Before activation, each collector registers its collection parameters with the `Manager`, including polling intervals, enable flags, and callback references. Once registration is complete, the engine locks its configuration and starts the aligned tickers. Further modifications are prevented to guarantee a stable scheduling environment during runtime.

At startup, all timing parameters are validated and normalized. Invalid or negative values are rejected or normalized to safe defaults, and the global quantum is verified to be strictly positive. Polling intervals and buffer windows are cross-checked to ensure consistency across collectors, and derived values such as buffer sizes are recomputed from the validated configuration. This guarantees deterministic timing behavior even under partial or malformed configuration files.

The configuration layer also provides flexible control over measurement cadence. Polling periods for individual collectors can be adjusted independently, allowing users to balance temporal precision against system overhead. The default parameters represent a high-frequency but safe baseline: 50 ms for RAPL, 50 ms for eBPF, 200 ms for GPU, and 1 s for Redfish telemetry. All tickers are aligned to the global

epoch defined by the monotonic clock, ensuring that these differences in cadence do not lead to drift over time.

Engine termination is context-driven: cancellation of the parent context signals all tickers to stop, after which the manager waits for all goroutines to complete. This unified shutdown mechanism ensures a clean and deterministic teardown sequence without leaving residual workers or buffers in undefined states.

5.7.5 Discussion and Limitations

The timing engine establishes the foundation for Tycho’s decoupled and fine-grained metric collection. By aligning all collectors to a shared epoch while allowing individual polling intervals, it eliminates the rigid synchronization that limited Kepler’s temporal accuracy. This design provides a lightweight yet deterministic coordination layer, enabling heterogeneous telemetry sources to contribute time-consistent samples at their native cadence.

The engine’s strengths lie in its simplicity and extensibility. Each collector operates independently, governed by its own aligned ticker, while context-driven lifecycle control ensures deterministic startup and shutdown. Because callbacks perform minimal, non-blocking work, jitter remains bounded even at high polling frequencies. This structure scales naturally with the number of collectors and provides a separation between timing logic, collection routines, and subsequent analysis stages.

Nevertheless, several practical limitations remain. The current implementation assumes a stable system clock and does not compensate for jitter introduced by the Go runtime or external scheduling delays. Collectors are expected to execute quickly; long-running or blocking operations may distort effective sampling intervals. Moreover, the engine’s alignment is restricted to a single node and does not extend to multi-host synchronization, which would require external clock coordination. At very high sampling rates, the cumulative scheduling overhead may also become non-negligible on resource-constrained systems.

Despite these constraints, the timing engine represents a decisive architectural improvement over Kepler’s fixed-interval model. It provides the temporal backbone for Tycho’s data collection pipeline and enables accurate, high-resolution correlation across diverse telemetry sources. The following section, § 5.8, describes how these samples are buffered and retained for subsequent analysis, completing the temporal layer that underpins Tycho’s measurement and attribution framework.

5.8 Ring Buffer Implementation

5.8.1 Overview

Tycho employs a per-metric ring buffer to store recent collection ticks produced by the individual collectors. Each collector owns a dedicated buffer that maintains a fixed number of entries, replacing the oldest values once full. This approach provides predictable memory usage and allows fast, allocation-free access to recent measurement histories. All ticks are stored in chronological order and include a monotonic epoch, ensuring consistent temporal alignment with the timing engine.

The buffers are primarily used as transient storage for downstream analysis, enabling energy and utilization data to be correlated across metrics without incurring synchronization overhead.

5.8.2 Data Model and Sample Types

Each ring buffer is strongly typed and holds a single metric-specific tick structure. These tick types encapsulate all data collected during one polling interval and embed the `SampleMeta` structure, which records Tycho's monotonic epoch. Depending on the metric, a tick may contain simple scalar values (e.g., total node power) or collections of per-entity deltas (e.g., per-process counters, per-GPU readings, or per-domain energy data). For example, a `RaplTick` stores per-socket energy deltas across all domains, while a `BpfTick` aggregates process-level counters and hardware event deltas observed during that tick. This typed approach simplifies access and ensures that all metric data (regardless of complexity) can be correlated on a uniform temporal axis defined by the timing engine.

5.8.3 Dynamic Sizing and Spare Capacity

The capacity of each ring buffer is determined dynamically at startup from the configured buffer window and the polling interval of the corresponding collector. This calculation is performed by the `SizeForWindow()` function, which estimates the number of ticks required to represent the desired time window and adds a small margin of spare capacity to tolerate irregular sampling or short bursts of delayed polls. As a result, each buffer maintains a stable temporal horizon while avoiding premature overwrites during transient load variations. If configuration changes occur, buffers can be resized at runtime, preserving the most recent entries to ensure data continuity across reinitializations.

5.8.4 Thread Safety and Integration

Each ring buffer can be wrapped in a synchronized variant to ensure safe concurrent access between collectors and analysis routines. The synchronized type, `Sync[T]`, extends the basic ring with a read-write mutex, allowing simultaneous readers while protecting write operations during tick insertion. In practice, collectors append new ticks concurrently to their respective synchronized buffers, while downstream components such as the analysis engine or exporters read snapshots asynchronously. A central `Manager` maintains references to all buffers, handling creation, resizing, and typed access. This design provides deterministic retention and thread safety without introducing locking overhead into the collectors themselves, keeping the critical path lightweight and predictable.

5.9 Calibration

Calibration in Tycho serves two distinct purposes: determining suitable polling intervals for hardware interfaces with irregular publish behaviour, and quantifying the delay between workload onset and observable changes in a given metric. Calibration is applied only where hardware characteristics exhibit variability that materially affects temporal alignment or accuracy. Where metric sources are stable, low-latency, or analytically understood, Tycho uses fixed, justified settings instead of dynamic calibration.

In practice, Tycho performs calibration for a small subset of collectors:

- **Polling-frequency calibration** is required only for GPU and Redfish power metrics, whose publish cadence is hardware-controlled and irregular. eBPF metrics are event-driven and do not require calibration, and RAPL counters update at sub-millisecond granularity with well-characterised behaviour, making calibration unnecessary.
- **Delay calibration** is performed exclusively for GPU power metrics, where internal averaging and buffered updates introduce measurable reaction latency. RAPL and eBPF have negligible or analytically bounded delay at Tycho’s sampling scale, and Redfish delay is too irregular and too coarse for meaningful calibration.

All remaining collectors operate with fixed, analysis-driven parameters. The following subsections describe Tycho’s calibration strategy and procedures in detail.

5.9.1 Polling-frequency Calibration

Polling-frequency calibration identifies a suitable sampling interval for sources whose publish cadence is neither fixed nor documented. For some collectors (e.g. RAPL, eBPF), the hardware already provides reliable or sufficiently fast update behaviour, making calibration unnecessary. For others (GPU, Redfish), Tycho uses brief hyper-polling phases to infer the effective update rhythm before normal collection begins.

5.9.1.1 eBPF Polling frequency calibration

Tycho does not perform a dedicated polling-frequency calibration for eBPF-based utilization metrics. eBPF events can be sampled at arbitrarily high rates, and their timing does not depend on hardware update intervals. Instead, Tycho aligns eBPF sampling with the RAPL polling frequency to maintain temporal consistency across collectors. Allowing shorter eBPF intervals would provide limited additional benefit while increasing processing overhead, so eBPF adopts the same lower bound as the CPU energy path and does not require separate calibration.

5.9.1.2 RAPL Polling frequency calibration

RAPL updates energy counters at sub-millisecond granularity, but sampling too aggressively introduces noise and diminishes measurement quality. Accuracy is further affected by optional energy filtering mechanisms that reduce fine-grained observability[26, Table 2-2]. Jay et al. found that sampling slower than 50 Hz keeps relative error below 0.5%[24]. Tycho imposes a minimum RAPL polling interval of 50 ms and treats any faster sampling as unnecessary. Because this bound is derived from hardware behaviour rather than runtime variability, Tycho does not include a polling-frequency calibration mechanism for RAPL.

5.9.1.3 GPU Polling frequency calibration

Before enabling regular GPU collection, Tycho measures the effective publish cadence of NVML power metrics. Rather than searching over candidate periods, it uses a short *hyperpoll* phase: for the duration of the calibration window, Tycho queries each GPU at a fixed, conservatively fast interval and simply counts how often it sees

a new, valid NVML update. From these timestamps it derives inter-arrival gaps and summarises them (via the median) into an estimated publish interval per device.

This converts the problem into “hits over time”: if a GPU produces n distinct updates over a calibration window of length T , the observed publish cadence is approximately T/n , refined by looking at the distribution of individual gaps rather than a single average. Tycho then recommends a per-device polling interval based on this estimate and finally adopts the most conservative (fastest) setting across all GPUs as the node-wide GPU polling period. This approach keeps the implementation simple while ensuring that subsequent GPU collection runs fast enough to see every NVML update without imposing unnecessary overhead.

5.9.1.4 Redfish Polling frequency calibration

Redfish power readings are coarse and highly irregular. Publish intervals may vary from sub-second to multi-second gaps, and this variability is further amplified on BMCs that expose multiple chassis or subsystems. Tycho therefore applies a simplified calibration procedure similar to the GPU polling calibration, but adapted to the characteristics of Redfish.

During calibration, Tycho hyperpolls Redfish at the minimum polling interval (500 ms) for a short window (60 seconds). Every newly observed Redfish update (from any chassis exposed by the same BMC) contributes an inter-arrival gap. Using the median of these gaps provides a robust estimate of the typical publish interval while naturally reflecting multi-chassis setups: if one chassis updates faster than others, the calibration converges to that faster cadence, ensuring that no subsystem is undersampled.

Based on this estimate, Tycho selects an operational polling period:

- Without continuous heartbeat, the median publish interval (clamped to 500 ms) is used directly.
- With continuous heartbeat enabled, Tycho selects a smaller polling interval (alf the median), allowing the collector to detect new samples promptly and maintain accurate freshness tracking despite Redfish’s inherent timing jitter.

This yields a coarse but sufficient estimate of the underlying BMC cadence while relying on the adaptive heartbeat mechanism during normal operation to maintain temporal coherence across all chassis.

5.9.2 Delay Calibration

Delay calibration determines the time interval between the start of a workload and the first measurable reaction in the corresponding hardware metric. Because Tycho itself does not execute workloads on the host and does not have direct access to specialised hardware resources, delay calibration must be performed by external scripts that run on the bare-metal node. Each calibration attempt begins with an idle period until the metric reaches a stationary state, followed by a controlled workload with a known start time. The delay is the earliest sample that exceeds the idle baseline by a detectable margin. Since many hardware metrics apply internal averaging or have irregular publish cycles, a single run is not sufficient. Multiple runs are required to

obtain a stable distribution. Tycho uses either the minimum or the fifth percentile of observed delays. The minimum reflects the earliest possible reaction. The fifth percentile can be used when the minimum appears to be an outlier.

5.9.2.1 GPU delay calibration

GPU delay calibration uses a dedicated script that generates a controlled GPU workload and monitors NVML power readings. A preliminary attempt relied on `gpu-burn`[59], but this tool carries a non-negligible startup delay that obscures the true hardware reaction time. To address this, the calibration mechanism was reimplemented with Numba[60], which allows the script to launch a custom floating-point kernel with exact control over the workload timing.

The script alternates between idle and active periods. During idle periods, NVML power is sampled until the readings reach a stable baseline, and only the final portion of the idle window is used for statistical analysis. During active periods, the Numba kernel saturates the GPU's compute units while the script continually samples NVML power. The delay is identified as the first sample that exceeds the idle baseline by a small, adaptively computed threshold. Because NVML power reports are averaged over approximately one second, many runs are required to gather a suitable distribution of delays. The default configuration uses 15 seconds of idle time, 15 seconds of active workload, a sampling interval of 50 milliseconds, and 100 runs.

5.9.2.2 RAPL delay calibration

No dedicated delay calibration is planned for RAPL. With the fast update frequency of RAPL energy counters, access latency is negligible. Although very early work criticised timing characteristics at sub-millisecond resolution[23], later studies generally consider RAPL accurate for the time scales relevant to energy modelling. Tycho enforces a minimum collection interval of 50 milliseconds because RAPL readings are noisy at very short intervals[21]. At this granularity any residual delay is small compared to the sampling window and does not meaningfully affect alignment. Explicit delay calibration would therefore provide minimal benefit.

5.9.2.3 Redfish delay calibration

Redfish presents a fundamentally different problem. Power readings are published slowly, with irregular inter-arrival times, and may skip updates entirely. An earlier empirical study reported delays of roughly 200 milliseconds[4], but also noted substantial variability across systems. Additional indeterminism arises from the network path and the unknown internal behaviour of the BMC. Since Tycho already mitigates staleness through its freshness mechanism, explicit delay calibration is neither feasible nor useful. Redfish is therefore treated as a coarse, low-resolution metric, appropriate for slow global trends but not for fine-grained timing.

5.9.2.4 eBPF Metrics delay calibration

eBPF-based utilisation metrics behave differently. They are collected directly in kernel context and do not involve additional publish intervals or device-side buffering. Their effective delay is negligible relative to Tycho's sampling windows, so no delay calibration is required.

5.10 Metadata Subsystem

Tycho introduces a dedicated metadata subsystem that provides an accurate, temporally aligned view of the node’s execution state. It follows the general Tycho design principles introduced in § ??: separation of concerns, accuracy-first data selection, and consistent correlation via monotonic timestamps. In contrast to *Kepler*, where metadata handling is tightly coupled to the individual metric collectors and suffers from the limitations discussed in § ?? and § ??, Tycho treats metadata as an independent architectural layer with its own storage and timing model.

5.10.1 Scope of Metadata

The subsystem aggregates all information required for correct and high-fidelity attribution. Rather than collecting only the minimal subset, Tycho records all metadata that materially improves attribution accuracy or interpretability. This includes:

- Process identity and attributes: PID, command name, cgroup, start time, and container association.
- Container and pod identity: container ID, container name, pod name, namespace, and basic lifecycle state.
- Kubelet-derived status: running, terminating, completed, or evicted pods and containers.
- Optional cAdvisor metadata: CPU, memory, and IO-level container usage counters for cross-validation and filtering.

Each of these sources contributes a partial view; the metadata subsystem maintains a unified, time-aligned representation by merging them into a shared store.

5.10.2 Positioning Within Tycho

Metadata collection is fully decoupled from power and utilization sampling. Collectors run on lightweight wall-clock intervals and push updates into a central store, while the analysis layer retrieves all required metadata when performing attribution. This prevents temporal entanglement with high-frequency collectors and avoids the failure modes observed in prior systems where stale container or pod state leaked into energy attribution.

5.10.3 Metadata Store and Lifetime Management

All metadata produced by Tycho’s collectors is written into a shared in-memory store that represents the node’s recent execution context. The store maintains three independent maps for processes, containers, and pods, each keyed by a stable identifier. Every entry is annotated with two timestamps: a monotonic timestamp for correlation with power and utilization samples, and a wall-clock timestamp used for enforcing the same horizon that governs Tycho’s power and utilization buffers.

The store maintains no long-term history. Instead, it retains a short rolling window of entries whose timestamps fall within the same horizon used by Tycho’s power and utilization buffers; the metadata retention period is therefore exactly the configured `maxAge`. Within this window, the analysis layer can reconstruct a coherent,

time-aligned view of processes, containers, and pods for any attribution interval. Collectors only insert or update metadata; they never delete entries directly.

Removal is delegated entirely to a horizon-based garbage collector. During each garbage-collection pass, the store removes entries whose wall-clock timestamp is older than the configured horizon. This ensures that terminated or deleted entities remain visible long enough for overlapping attribution windows to resolve correctly, while preventing stale metadata from influencing later analysis. When collectors stop producing updates, the store drains itself naturally after the horizon expires. The result is deterministic freshness guarantees, bounded memory usage, and a simple, robust metadata lifecycle.

The following subsections describe the individual metadata collectors that populate this store.

5.10.4 Process Metadata Collector

The process metadata collector maintains a short-horizon view of all processes running on the node. Its purpose is to provide the analysis layer with enough contextual information to correlate per-process activity with container and pod identities, while avoiding any direct dependency on power or utilization collectors.

The collector performs a best-effort enumeration of all processes via `/proc`. For each PID it records a minimal set of attributes useful for later energy attribution: a stable per-boot identifier (`PID`, `StartJiffies`), a container mapping, and a human-readable command name. Metadata is timestamped with monotonic and wall-clock time and inserted into the central metadata store, which enforces a sliding time horizon through periodic garbage collection.

Reused functionality from Kepler Tycho reuses Kepler's cgroup resolution logic to map processes to container identifiers. This logic extracts normalized container IDs from cgroup paths and distinguishes pod containers from system processes. Tycho integrates this component without modifying its behaviour.

Tycho-specific additions Tycho introduces a new, self-contained metadata subsystem and defines the process collector as an independent, low-overhead component. In contrast to Kepler, Tycho does not combine process enumeration with resource accounting. The collector records a stable process start token (`StartJiffies`), used only to disambiguate PID reuse, and stores all metadata in a dedicated in-memory store shared across all metadata collectors. No attribution logic is implemented at this stage.

The process collector intentionally keeps its scope minimal. Higher-level enrichment such as pod metadata, QoS class or container state is delegated to the kubelet and cgroup-based container collectors described in § 5.10.5.

5.10.4.1 Collected Metrics

The following table 5.7 shows the collected metrics.

Field	Source	Description
<i>Process identity</i>		
PID	/proc	Numeric process identifier; unique at any moment but reused over time.
StartJiffies	/proc/<pid>/stat	Kernel start time of the process in clock ticks (jiffies), used to detect PID reuse.
<i>Container and system classification</i>		
Container ID	Kepler cgroup resolver	Normalized container identifier for pod processes; <code>system_processes</code> for host and kernel processes.
Command	/proc/<pid>/comm	Short command name for debugging and manual inspection.
<i>Timestamps</i>		
LastSeenMono	Monotonic timebase	Timestamp aligned with metric collectors.
LastSeenWall	Controller timestamp	Wall-clock timestamp for GC.

TABLE 5.7: Process metadata collected by the process collector

5.10.5 Kubelet Metadata Collector

The kubelet metadata collector provides Tycho with an authoritative, scheduler-consistent view of all pods and containers currently known to the node. It complements the process collector by supplying the semantic information required for correct attribution: pod identity, lifecycle state, container status, and resource specifications. Unlike the process collector, which observes execution from the operating system perspective, the kubelet collector captures the Kubernetes control-plane perspective.

The collector periodically retrieves the full pod list from the kubelet’s /pods endpoint and extracts only metadata that cannot be reconstructed later. All entries are timestamped with Tycho’s monotonic timebase and inserted into the shared metadata store, where they remain available for attribution until removed by horizon-based garbage collection.

Reused functionality from Kepler Tycho reuses Kepler’s container-ID normalization logic to extract runtime container identifiers from kubelet status fields. The use of the kubelet’s PodStatus API as the ground truth for container lifecycle state is also conceptually inherited from Kepler, but Tycho decouples it from resource accounting and avoids Kepler’s tightly coupled watcher design.

Tycho-specific additions Tycho substantially extends the kubelet collector relative to Kepler:

- Pod-level and container-level metadata are stored in a dedicated subsystem with monotonic timestamps, ensuring temporal alignment with power and utilization sampling.
- Resource requests and limits from `pod.spec` are recorded for both containers and aggregated pods, preserving information that disappears once pods terminate.

- Controller owner references (e.g. ReplicaSet, DaemonSet) are captured to support later grouping and attribution without encoding any classification logic in the collector.
- Ephemeral and init containers are fully supported, and termination state and exit codes are recorded to prevent attribution to completed workloads. Terminated containers remain in the store until the horizon expires, ensuring correct attribution for analysis windows that overlap their termination.

No scheduling decisions, classification, or attribution logic is executed at collection time; all interpretation is deferred to the analysis layer.

5.10.5.1 Collected Metrics

The kubelet collector records per-pod and per-container metadata as shown in Tables 5.8 and 5.9. Only fields that cannot be reliably reconstructed later are persisted.

Field	Source	Description
<i>Pod identity</i>		
PodUID	Kubelet PodList	Stable pod identifier for correlation and container grouping.
PodName, Namespace	Kubelet PodList	Human-readable pod identity and namespace.
<i>Lifecycle and scheduling context</i>		
Phase	PodStatus	Coarse pod state (Pending, Running, Succeeded, Failed).
QoSClass	PodStatus	Kubernetes QoS classification (Guaranteed, Burstable, BestEffort).
OwnerKind / OwnerName	Pod metadata	Controller reference (e.g. ReplicaSet, DaemonSet).
<i>Resource specifications</i>		
Requests (CPU, Memory)	pod.spec.containers	Aggregate pod-level requests following Kubernetes scheduling semantics.
Limits (CPU, Memory)	pod.spec.containers	Aggregate pod-level limits following Kubernetes scheduling semantics.
<i>Timestamps</i>		
LastSeenMono	Monotonic timebase	Timestamp aligned with metric collectors.
LastSeenWall	Controller timestamp	Wall-clock timestamp for GC.

TABLE 5.8: Pod metadata collected by the kubelet collector

Field	Source	Description
<i>Container identity</i>		
ContainerID	PodStatus	Normalized container identifier.
ContainerName	PodStatus	Declared container name within pod.
<i>Lifecycle state</i>		
State	ContainerStatus	Fine-grained state (Running, Waiting, Terminated).
ExitCode	ContainerStatus	Termination exit code when available.
<i>Resource specifications</i>		
Requests (CPU, Memory)	pod.spec.containers	Container-level resource requests; preserved for terminated containers.
Limits (CPU, Memory)	pod.spec.containers	Container-level resource limits.
<i>Timestamps</i>		
LastSeenMono	Monotonic timebase	Timestamp aligned with metric collectors.
LastSeenWall	Controller timestamp	Wall-clock timestamp for GC.

TABLE 5.9: Container metadata collected by the kubelet collector

5.10.6 Why Tycho Does Not Require cAdvisor for Container Enumeration

KubeWatt integrates *cAdvisor* to correct several metadata inconsistencies observed in Kepler, in particular the presence of slice-level cgroups and terminated containers that continued to appear in resource usage reports. In KubeWatt’s design, *cAdvisor* serves primarily as a *filter*: it exposes only real, runtime-managed containers and thereby removes artefacts such as `kubepods.slice` or QoS slices that would otherwise distort CPU attribution [52].

Tycho does not require this mechanism. The root causes that motivated the use of *cAdvisor* in KubeWatt are addressed structurally by Tycho’s metadata subsystem: container and pod identity are obtained exclusively from the *kubelet*, process–container association is resolved using a stable cgroup parser, and all metadata is managed within a unified, timestamped store with deterministic garbage collection. As a result, Tycho never encounters the slice-level or terminated-container artefacts that *cAdvisor* was used to filter out.

This does not preclude using *cAdvisor* as an optional enrichment source for slowly changing contextual metrics (for example throttling counters or memory usage), but its role as a correctness or filtering layer is superseded by Tycho’s dedicated metadata architecture.

Abstract

The growing energy demands of data centers have positioned energy efficiency as a critical concern in modern cloud computing. As containerization becomes the dominant approach for deploying scalable workloads, understanding the energy consumption of individual containers gains strategic relevance. However, accurately attributing energy usage to containerized workloads remains a complex and largely unsolved challenge due to hardware abstraction, shared resource utilization, and limited telemetry visibility.

This thesis investigates the theoretical foundations, methodological challenges, and existing approaches to container-level energy consumption measurement. Emphasizing bare-metal Kubernetes environments, the study systematically explores system-level energy measurement techniques, the complexities of attributing node-level energy to individual containers, and the limitations of current measurement tools. Rather than developing a new estimation tool, this work provides a structured analysis of existing solutions, highlighting methodological gaps, validation challenges, and critical design considerations for future research and tool development.

The findings offer a consolidated understanding of the technical factors influencing container energy attribution and outline practical recommendations for advancing energy transparency in containerized cloud infrastructures.

Chapter 1

Introduction

1.1 Cloud Computing and its Impact on the Global Energy Challenge

Global energy consumption is rising at an alarming pace, driven in part by the accelerating digital transformation of society. A significant share of this growth comes from data centers, which form the physical backbone of cloud computing. While the cloud offers substantial efficiency gains through resource sharing and dynamic scaling, its aggregate energy footprint is growing rapidly. Data centers accounted for around 1.5% (approximately 415 TWh) of the world's electricity consumption in 2024 and are set to more than double by 2030[61]. This figure slightly exceeds Japan's current electricity consumption.

This increase is fueled by the rising demand for compute-heavy workloads such as artificial intelligence, large-scale data processing, and real-time services. Meanwhile, traditional drivers of efficiency (such as Moore's law and Dennard scaling) are slowing down[62, 63]. Improvements in data center infrastructure, like cooling and power delivery, have helped reduce energy intensity per operation[64], but these gains are approaching diminishing returns. As a result, total data center energy use is expected to grow faster than before, as efficiency per unit of compute continues to improve more slowly[65]. As containerized workloads form a significant and growing fraction of data center operations, understanding their energy impact is of increasing relevance.

1.1.1 Rise of the Container

Containers have become a core abstraction in modern computing, enabling lightweight, fast, and scalable deployment of applications. Compared to virtual machines, containers impose less overhead, start faster, and support finer-grained resource control. As such, they are widely used in microservice architectures and cloud-native environments[66].

This trend is amplified by the growing popularity of Container-as-a-Service (CaaS) platforms, where containerized workloads are scheduled and managed at high density on shared infrastructure. Kubernetes has become the de facto orchestration tool for managing such workloads at scale. While containers are inherently more energy-efficient than virtual machines in many scenarios[67], their widespread use introduces a critical complication: accurately understanding and attributing their energy

consumption. Despite their operational advantages, containers obscure energy usage due to their shared-resource architecture, making transparent monitoring and assessment of their true energy efficiency significantly more difficult.

1.1.2 Thesis Context and Motivation

This thesis is part of the Master's program in Computer Science at the Zurich University of Applied Sciences (ZHAW) and represents the second of two specialization projects ("VTs"). The preceding project (VT1) focused on the practical implementation of a test environment for energy efficiency research in Kubernetes clusters. This thesis (VT2) is intended to explore the theoretical and methodological aspects of container energy consumption measurements in detail.

Furthermore, this thesis builds upon prior works focused on performance optimization and energy measurement. EVA1 covered topics such as operating system tools, statistics, and eBPF, while EVA2 explored energy measurement in computer systems, covering energy measurement in computer systems at the hardware, firmware, and software levels. This thesis builds upon these foundations, focusing specifically on the problem of container-level energy consumption measurement.

1.1.3 Use of AI Tools

During the writing of this thesis, *ChatGPT*[68] (Version 4o, OpenAI, 2025) was used as an auxiliary tool to enhance efficiency in documentation and technical writing. Specifically, it assisted in:

- Assisting in LaTeX syntax corrections and document formatting.
- Improving clarity and structure in selected technical explanations.
- Supporting minor code analysis and debugging tasks.

All AI-generated content was critically reviewed, edited, and adapted to fit the specific context of this thesis. **AI was not used for literature research, conceptual development, methodology design, or analytical reasoning.** The core ideas, analysis, and implementation details were developed independently.

1.1.4 Container Energy Consumption Measurement Challenges

Containerized environments introduce fundamental challenges to energy consumption measurement. Unlike virtual machines, containers share the host operating system kernel and underlying hardware resources. This shared architecture obscures the direct relationship between a specific container and the physical energy consumed, making isolated measurement infeasible.

While modern processors expose hardware-level telemetry via interfaces such as Intel's Running Average Power Limit (RAPL), these provide only node-level or component-level insights. In addition, such telemetry is typically inaccessible from within containers, particularly in multi-tenant or cloud-hosted environments. Public cloud providers often aggregate or abstract energy-related data, further limiting observability.

Attribution of energy consumption to containers is complicated by concurrent resource sharing. CPU cores, memory, network interfaces, and storage systems serve multiple containers simultaneously. Available resource utilization metrics, such as CPU time, memory usage, or performance counters, provide indirect signals that could be used for energy attribution, but don't directly attribute it.

Various tools attempt to model container-level power consumption by correlating resource utilization with node-level energy telemetry. However, these models are often simplistic, opaque, or specific to particular hardware setups, and lack systematic validation.

Collectively, these factors result in a complex, multi-layered measurement problem: translating node-level energy consumption into accurate, container-level usage estimates within modern cloud infrastructures.

1.1.5 Scope and Research Questions

This thesis investigates the theoretical and practical landscape of container energy consumption measurement, focusing on the attribution of energy usage within bare-metal Kubernetes environments. Instead of proposing a novel measurement tool or developing a new energy estimation model, the thesis aims to systematically analyze the problem space and existing solutions.

The objective is to identify the methodological, technical, and practical factors that influence accurate container-level energy measurement. The study evaluates how existing tools address these challenges and highlights unresolved issues that hinder reliable and standardized energy attribution in containerized systems.

To guide this exploration, the following research questions are posed:

- **RQ1:** What are the fundamental challenges that prevent accurate measurement of container-level energy consumption?
- **RQ2:** Which methods, metrics, and models currently support container energy consumption estimation, and how do they address the attribution problem?
- **RQ3:** How do existing tools implement container-level energy consumption estimation, and what are the limitations of their approaches?

Rather than explicitly answering these questions in isolation, the thesis addresses them throughout its analysis: These questions structure the thesis' analytical approach. A detailed overview of the thesis structure is provided in the following section.

1.1.6 Terminology: Power and Energy

In this thesis, the physical units power (measured in watts) and energy (measured in joules) are used interchangeably where appropriate. While these units describe distinct physical quantities (energy representing the total amount of work performed, and power representing the rate of energy usage over time), the time interval in question is generally known or defined in all relevant contexts, rendering conversion between them trivial.

As a result, discussions of container-level energy consumption, power usage, and energy attribution may reference either energy or power depending on context, without introducing ambiguity. Where necessary, the specific unit used is stated explicitly.

1.1.7 Contribution and Structure of the Thesis

This thesis contributes a structured, theory-focused exploration of container-level energy consumption measurement. Rather than presenting a novel tool or proposing a specific implementation concept, it synthesizes existing methods, models, and challenges relevant to this field. Its primary contribution lies in analyzing how energy consumption can be measured and attributed to individual containers in bare-metal Kubernetes environments, highlighting limitations, and identifying open challenges for future work.

The thesis is structured as follows:

- **Chapter 2** introduces the fundamentals of server energy consumption, including hardware-level telemetry, component-level energy behaviors, and system power management mechanisms.
- **Chapter 3** analyzes the attribution problem of mapping node-level energy consumption to individual container workloads, identifying core challenges and influencing factors.
- **Chapter 4** surveys existing tools and approaches that attempt to estimate container-level energy consumption, assessing their methodologies and limitations.
- **Chapter 5** synthesizes the findings, identifies open questions, and outlines recommendations for future research and tool development.

Both this thesis and the preceding implementation-focused project are publicly available in the PowerStack[1] repository on GitHub. While this thesis does not come with additional code, the repository contains Ansible playbooks for automated deployment, Kubernetes configurations, monitoring stack setups, and benchmarking scripts from the preceding thesis.

Chapter 2

State of the Art and Related Research

2.1 Energy Consumption Measurement and Efficiency on Data Center Level

Energy consumption and efficiency at the data center level have been well-studied to the point where various literature reviews have been published[3, 69]. Much of this research focuses on data center infrastructure (cooling and power), and with good reason, as infrastructure is responsible for a large share of total energy consumption. While a wide range of coarse-, medium-, and fine-grained metrics for data center energy consumption exist, most operators have concentrated on improving coarse-grained metrics, especially *Power Utilization Effectiveness (PUE)*, through infrastructure improvements. This has resulted in a PUE of 1.1 or lower in some cases[64]. Meanwhile, server energy efficiency has improved substantially, particularly for partial load and idle power[70]. This has allowed data center operators to improve energy efficiency simply by installing more efficient cooling and power systems and servers. Fine-grained metrics, such as server component utilization rates or speeds, were generally not used in the context of energy efficiency but rather as performance metrics to ensure customer satisfaction.

2.2 Energy Consumption Measurement on Server Level

As a result of the energy efficiency improvements of both data center infrastructure and server hardware mentioned in the previous section, attention has shifted towards evaluating actual server load energy efficiency. Efficiency gains at this level compound into further improvements at the data center level. The resource-sharing methods of modern cloud computing (and especially the use of containers) create significant opportunities for server workload optimization for energy efficiency, which in turn requires power consumption measurements for evaluation. In the context of containers on multi-core processors, measuring the energy consumption of the entire server is insufficient, as it does not allow attribution of consumed energy to specific containers or processes. While component-level power measurements provide finer granularity and could theoretically be modeled to reflect container energy consumption, they drastically raise complexity for several reasons:

- Component-level energy consumption measurement without external tools is

far from straightforward. While some components provide estimation models (e.g. Intel RAPL or *Nvidia Management Library* (NVML)), others can only be estimated using performance metrics. This invariably leads to large measurement uncertainties, especially due to hardware differences between generations and manufacturers.

- Attributing measured or estimated energy consumption to individual containers is itself a non-trivial problem: it requires fine-grained time synchronization between energy consumption and container resource usage due to the fast-switching nature of most server components during multitasking.
- A deep understanding of dynamic versus static energy consumption is required: depending on the attribution model, a container might account not only for the energy it actively used but also for a fraction of the energy consumed by shared overhead, such as shared hardware components or system resources (such as the Kubernetes system architecture). This idea can be extended further: containers could potentially be penalized for unused server resources, as unused capacity still consumes energy. These different attribution models lead to a broader debate about the goals of the measurements.
- Any server-level power models used to estimate the relationship between individual component energy consumption suffer from the variety of server configurations, due to specialization such as storage-, GPU-, or memory-optimized servers.

In a systematic review of cloud server power models, Lin et al.[2] categorize power collection methods into four categories:

Key	Value	Description	Deployment Difficulty	Data Granularity	Data Credibility
Based on instruments	Installation of extra devices	Bare-metal machines	Easy	Machine Level	Very high
Based on dedicated acquisition system	Specialized systems	Specified models of machines	Difficult	Machine or component-level	High
Based on software monitoring	Built-in power models	Bare-metal and virtual servers	Moderate	Machine, component, or VM level	Fair
Based on simulation	System simulation	Machine, component, or VM level	Easy	Machine, component, or VM level	Low

TABLE 2.1: Comparison of power collection methods for cloud servers

The following sections of this chapter aim to present the current state-of-the-art in the various fields of research related to the problem domains listed above, focusing on different measurement approaches: direct hardware measurements, in-band measurement techniques, and model-based estimation. The sections are organized by measurement approach, foregoing organization by server component. For this reason, § 2.7 provides a brief summary of component-specific energy consumption

measurement techniques.

2.3 Direct Hardware Measurement

2.3.1 Instrument-based Power Data Acquisition

Instrument-based data acquisition produces the highest data credibility at low granularity: these devices, installed externally (measuring the power supplied to the PDU) or internally (measuring the power flow between the PDU and motherboard), have been the source of information for a number of studies. The approach of simply measuring electric power at convenient hardware locations using dedicated equipment can, of course, be extended to provide additional granularity. For example, Desrocher et al.[8] custom-created a DIMM extender fitted with Hall-sensor resistors and a Linux measurement utility to measure the power consumed by a DIMM memory module at a 1kHz sampling rate, using a *WattsAppPro?* power meter and a *Measurement Computing USB.1208FS-Plus* data acquisition board.

This highlights a fundamental truth of instrument-based data collection: while it is possible to implement a measuring solution that provides high-granularity and high-sampling rate power data, this requires immense effort, as such solutions are not available off-the-shelf. Unsurprisingly, this is most valuable for benchmarking or validation (Desrochers et al. used their setup to validate Intel RAPL DRAM power estimations on three different systems). However, this methodology is currently unsuitable for deployment in data center servers due to its poor scalability and prohibitive costs. Hence, the primary role of instrument-based power data acquisition is as a benchmarking and validation tool for research and development.

2.3.2 Dedicated Acquisition Systems

2.3.2.1 BMC Devices, IPMI and Redfish

Some manufacturers have developed specialized power data acquisition systems for their own server products. The baseboard management controller (BMC) is a typical dedicated acquisition system usually integrated with the motherboard, typically as part of the Intelligent Platform Management Interface (IPMI)[2]. It can be connected to the system bus, sensors, and a number of components to provide power and temperature information about the CPU, memory, LAN port, fan, and the BMC itself. Some comprehensive management systems, such as Dell iDRAC or Lenovo xClarity, have been further developed to provide high-quality, fine-grained power data due to their close integration between system software and underlying hardware. BMC devices on modern servers often offer IPMI or Redfish interfaces. While these interfaces use the same physical sensors, their implementations differ significantly, with Redfish generally offering higher accuracy (e.g. through the use of higher-bit formats, whereas IPMI often uses 8-bit raw numbers).

In the context of container power consumption estimation, IPMI implementations occupy an interesting role. In 2016, Kavanagh et al.[11] found the accuracy of IPMI power data to be relatively low when compared with an external power meter, mainly due to the large measurement window size of 120 to 180 seconds and the inaccurate assessment of idle power. They concluded that IPMI power data was still useful when a longer averaging window was used and the initial data points were discounted. In a later study, they suggested combining the measurements of IPMI

and Intel RAPL (which they found to underestimate power consumption) for a reasonable approximation of true measurements[12]. Kavanagh's findings have been cited in various studies, often to argue against using IPMI for power measurement. When used, it is sometimes chosen simply because it was the "simplest power metric to read"[71] in the context of entire data centers.

Redfish is a modern out-of-band management system, first released in 2015 explicitly to replace IPMI[72]. It uses a RESTful API and JSON data format, making queries easier to perform via code. In 2019, Wang et al.[4] directly compared IPMI and Redfish power data to readings from a high-accuracy power analyzer and found Redfish to be more accurate than IPMI, with a MAPE of 2.9%, while also finding a measurement latency of about 200ms. They also found measurements to be more accurate in higher power ranges, which they attributed to the improved latency.

In conclusion, BMC power data acquired over Redfish provides a simple and comparatively easy way to measure system power based on various physical system sensors. Its greatest strength lies in easy implementation and general availability. In the context of container energy consumption, BMC power data lacks the short sampling rates necessary to measure a highly dynamic container setup but can prove useful as a validation or cross-reference dataset for longer intervals exceeding 120 seconds. Unfortunately, the data quality of BMC power data depends on the actual system, and power models can be significantly improved by initial calibration with an external power measurement device[11].

2.4 In-Band Measurement Techniques

In-band measurement techniques refer to methods of power consumption monitoring that utilize built-in telemetry capabilities of system components to collect energy usage data directly from within the host system. Unlike external power meters or BMCs like IPMI, which operate independently of the main system, in-band techniques leverage on-die sensors and software interfaces to gather power metrics in real-time. These techniques provide fine-grained data with minimal additional hardware, making them well-suited for scalable environments like Kubernetes clusters. However, their accuracy and granularity are often dependent on the hardware's internal estimation algorithms, which may introduce uncertainties compared to direct measurement methods.

2.4.1 ACPI

The *Advanced Configuration and Power Interface (ACPI)* is a standardized interface that facilitates power management and hardware configuration by allowing the operating system to control hardware states such as processor sleep, throttling, and performance modes [10]. It plays a significant role in processor performance tuning by exposing C-states (idle), P-states (performance), and T-states (throttling), which the OS can leverage to adjust the processor's activity, frequency, and voltage.

Although ACPI defines these power states, their actual implementation is processor-specific, and the interface does not provide real-time telemetry. As such, ACPI does not expose instantaneous power consumption values. Any attempt to estimate power based on ACPI would require detailed knowledge of processor-specific behavior, including the mapping between frequency, voltage, and power information

that is not exposed through ACPI. As a result, limited research has been conducted on this topic.

In theory, one could attempt to use ACPI's `_PSS` (Performance Supported States) table, which lists available P-states along with nominal voltage, frequency, and optionally estimated maximum power dissipation, to perform rough CPU power estimation. This method would involve tracking CPU residency in each performance state and applying simple integration models to estimate total energy. However, due to the static nature of `_PSS` entries and the lack of temporal precision, such estimates would be inherently coarse-grained and typically inaccurate for modern processors with dynamic voltage and frequency scaling or turbo modes.

Consequently, ACPI is rarely used in contemporary power estimation contexts. Its primary role remains in system configuration and power state control rather than accurate energy quantification. In modern Intel processors, the Running Average Power Limit (RAPL) interface provides a more appropriate solution for in-band power measurement. This makes RAPL the preferred tool for energy-aware computing research and production environments alike.

2.4.2 Intel RAPL

Intel Running Average Power Level (RAPL) is a Power Monitoring Counter (PMC)-based feature introduced by Intel that provides a way to monitor and control the energy consumption of various components within their processor package[73]. An adaptation of RAPL for AMD processors uses largely the same mechanisms and the same interface[74], although it provides less information than Intel's RAPL, offering no DRAM energy consumption[22]. Unfortunately, RAPL lacks detailed low-level implementation documentation, and the exact methodology of the RAPL calculations remains unknown[24].

Intel RAPL has been used extensively in research to measure energy consumption[20] despite some objections regarding its accuracy, which will be discussed in § 2.4.2.2 and § 2.4.2.3. The general consensus is that RAPL is *good enough* for most scientific work in the field of server energy consumption and efficiency. As Raffin et al.[16] point out, it is mostly used *like a black box without deep knowledge of its behavior*, resulting in implementation mistakes. For this reason, § 2.4.2.1 presents an overview of the RAPL fundamentals.

2.4.2.1 RAPL Measurement Methods

This subsection provides an overview of how RAPL works and is used. It is based on the Intel Architectures Software Developer's Manual[15, Section 16.10] and the works of Raffin et al. [16] (2024) and Schöne et al. [21] (2024).

Running Average Power Limit (RAPL) is a power management interface in Intel CPUs. Apart from power limiting and thermal management, it also allows measuring the energy consumed by various components (or *domains*). These domains include individual CPU cores, integrated graphics (in non-server CPUs), and DRAM, as well as the *package*, referring to the whole CPU die. While it initially used models to estimate energy use[17], it now uses physical measurements. The processor is divided into different power domains or "planes", representing specific components,

as seen in figure 2.1. Notably, not all domains are present in all systems: both client-grade systems feature the *Package* and *PP0 core* domains, server-grade processors typically do not show the *PP1 uncore* domain (typically used for integrated GPUs), and client-grade processors do not show the *DRAM* domain. The *PSYS* domain for the "whole machine" is ill-defined and only exists on client-grade systems. In an experiment with recent Lenovo and Alienware laptops, Raffin et al. found that the *PSYS* domain reported the total consumption of the laptop, including display, dedicated GPU, and other domains. Regardless, this thesis focuses on the RAPL power domains available to server-grade processors.

FIGURE 2.1: Hierarchy of possible RAPL domains and their corresponding hardware components. Domain names are in italic, and grayed items do not form a domain on their own. Items with an asterisk are not present on servers[16].

RAPL provides hardware counters to read the energy consumption (and set power limits) for each domain. The energy consumption is measured in terms of processor-specific "energy units" (e.g. $61\mu\text{J}$ for Haswell and Skylake processors). The counters are exposed to the operating system through model-specific registers (MSRs) and are updated approximately every millisecond. The main advantages of RAPL are that no external power meters are required, nor privileged access to the BMC (which could be used to power off the server). RAPL is more accurate than any untuned statistical estimation model.

Various measurement methods can be used to extract RAPL measurements. In a detailed comparison, Raffin et al.[16] outline their individual features and tradeoffs, summarized in figure 2.2b:

- **Lacking documentation:** Since there is no publicly available documentation of the low-level RAPL implementation, implementations are bound to suffer inaccuracies and inconsistencies due to a lack of understanding.
- **The Model-Specific Register (MSR) interface:** provides low-level access to RAPL energy counters but is complex and hardware-dependent. Developers must manually determine register offsets and unit conversions based on processor model and vendor documentation. This method lacks safeguards, requires

deep processor knowledge, and is error-prone, with incorrect readings difficult to detect. Although read-only access poses no risk to system stability, MSRs expose sensitive data and are thus restricted to privileged users (e.g. `root` or `CAP_SYS_RAWIO`). Fine-grained access control is not supported natively, though the `msr-safe` module offers limited mitigation.

- The **Power Capping (powercap)** framework is a high-level Linux kernel interface that exposes RAPL energy data through the sysfs filesystem, making it accessible from userspace. It simplifies energy measurements by automatically handling unit conversions and domain discovery, requiring minimal hardware knowledge. Though domain hierarchy can be confusing (especially with DRAM domains appearing nested under the package domain), powercap remains user-friendly and scriptable. It supports fine-grained access control via file permissions and offers good adaptability to hardware changes, provided the measurement tool doesn't rely on hard-coded domain structures.
- The **perf-events** subsystem provides a higher-level Linux interface for accessing RAPL energy counters as counting events. It supports overflow correction and requires less hardware-specific knowledge than MSR. Each RAPL domain must be opened per CPU socket using `perf_event_open`, and values are polled from userspace. While it lacks a hierarchical structure like powercap and may be harder to use in certain languages or scripts, it remains adaptable and robust across different architectures. Fine-grained access control is possible via kernel capabilities or `perf_event_paranoid` settings.
- **eBPF** enables running custom programs in the Linux kernel, and in this context, it is used to directly read RAPL energy counters from within kernel space, potentially reducing measurement overhead by avoiding user-kernel context switches. The implementation attaches an eBPF program to a CPU clock event, using `perf_event_open` to access energy counters and buffering results for userspace polling (as visualized in figure 2.2a). While offering the same overflow protection as regular perf-events, this approach is significantly more complex, prone to low-level errors (especially in C), and requires elevated privileges (`CAP_BPF` or `root`). It also lacks portability, as it demands manual adaptation to kernel features and domain counts, limiting its maintainability across systems.

(A) RAPL perf-event eBPF mechanism

mechanism	technical difficulty	required knowledge	safeguards	privileges	resiliency
MSR	medium	CPU knowledge	none	SYS_RAWIO cap. + msr module	poor
perf-events + eBPF	high (long, complicated code)	limited	overflows unlikely, many other possible mistakes	PERFMON and BPF capabilities	manual tweaks necessary for adaptation
perf-events	low	limited	good, overflows unlikely	PERFMON capability	good
powercap	low	limited	beware of overflows	read access to one dir	good, very flexible

(B) RAPL measurement mechanisms comparison

FIGURE 2.2: RAPL measurements: eBPF and comparison[16]

In their research, Raffin et al. conclude that all four mechanisms have small or negligible impact on the running time of their benchmarks. They formulate the following recommendations for future energy monitoring implementations:

- Measuring frequencies should be adapted to the state of the node to prevent high measurement overhead caused by reduced time spent in low-power states. Under heavy load, a high frequency can be used to capture more information.
- `perf-events` is the overall recommended measurement method, providing good efficiency, latency, and overflow protection. Powercap is less efficient but provides a simpler sysfs API.
- Even though `perf-events` and the eBPF measurement method appear to be the most energy-efficient, they are not recommended due to their complexity. For the same reason, the MSR method is not recommended, as it raises complexity while counter-intuitively being slower than `perf-events`.

RAPL MSRs can be read on some cloud computing resources (e.g. some Amazon EC2 instances), although the hypervisor traps the MSR reads, which can add to the polling delay. In EC2, the performance overhead also significantly increases to <2.5% (compared to <1% on standalone systems)[24].

2.4.2.2 RAPL Validation

Since its inception, RAPL has been the subject of various validation studies, with the general consensus that its accuracy could be considered "good enough"[16]. Notable works include Hackenberg et al., who in 2013 found RAPL accurate but missing timestamps[18], and in 2015 noted a major improvement to RAPL accuracy after Intel switched from a modeling approach to actual measurements for their Haswell architecture[17]. Desrochers et al. concluded in a 2016 RAPL DRAM validation study[8] that DRAM power measurement was reasonably accurate, especially on server-grade CPUs. They also found measurement quality to drop when measuring an idling system. Later, Alt et al.[19] tested DRAM accuracy of heterogeneous memory systems of the more recent Ice Lake-SP architecture and concluded that DRAM estimates behaved differently than on older architectures. They noted that RAPL overestimates DRAM energy consumption by a constant offset, which they attribute to the off-DIMM voltage regulators of the memory system.

A critical point in RAPL validation was the introduction of the Alder Lake architecture, marking Intel's first heterogeneous processor, combining two different core architectures from the Core and Atom families (commonly referred to as P-Cores and E-Cores) to improve performance and energy efficiency. While this heterogeneity can improve performance and energy efficiency, it also increases the complexity of scheduling decisions and power-saving mechanisms, adding to the already complex architecture, which features per-core Dynamic Voltage and Frequency Scaling (DVFS), idle states, and power limiting/thermal protection.

Schöne et al.[21] found RAPL in the Alder Lake architecture to be generally consistent with external measurements but exhibiting lower accuracy in low-power scenarios. The following figure 2.3 shows these inaccuracies, albeit tested on a consumer-grade Intel Core i9-12900K processor measured at the base frequency of 0.8GHz.

FIGURE 2.3: RAPL and reference power consumption sampled at 100 ms / 50 ms intervals, respectively. Double precision matrix multiplication kernel at 0.8GHz running for 60s each at increasing number of active threads[21].

2.4.2.3 RAPL Limitations and Issues

Several limitations of RAPL have been identified in various research works. Since RAPL is continually improved by Intel as new processors are released, some of these issues have since been improved or entirely solved.

- **Register overflow:** The 32-bit register can experience an overflow error[16, 23]. This can be mitigated by sampling more frequently than the register takes to overflow. This interval can be calculated using the following equation:

$$t_{\text{overflow}} = \frac{2^{32} \cdot E_u}{P} \quad (2.1)$$

Here, E_u is the energy unit used ($61\mu\text{J}$ for Haswell), and P is the power consumption. On a Haswell processor consuming 84W, an overflow would occur every 52 minutes. Intel acknowledges this in the official documentation, stating that the register has a *wraparound time of around 60 seconds when power consumption is high*[15]. This is solvable with a simple correction, provided that the measurement intervals are small enough: for two successive measurements m_{prev} and m_{current} , the actual measured difference is given by

$$\Delta m = \begin{cases} m_{\text{current}} - m_{\text{prev}} + C & \text{if } m_{\text{current}} < m_{\text{prev}} \\ m_{\text{current}} - m_{\text{prev}} & \text{otherwise} \end{cases} \quad (2.2)$$

where C is a correction constant that depends on the chosen mechanism:

- **DRAM accuracy:** DRAM accuracy can only reliably be used for the Haswell architecture[8, 19, 23] or newer, and may still exhibit a constant power offset (attributed to the voltage regulator power loss of the memory system).

Mechanism	Constant C
MSR	<code>u32::MAX</code> , i.e., $2^{32} - 1$
perf-events	<code>u64::MAX</code> , i.e., $2^{64} - 1$
perf-events with eBPF	<code>u64::MAX</code> , i.e., $2^{64} - 1$
powercap	Value given by the file <code>max_energy_uj</code> in the sysfs folder for the RAPL domain

TABLE 2.2: RAPL overflow correction constant

- **Unpredictable timings:** While Intel documentation states that the RAPL time unit is 0.976ms, the actual intervals may vary. This is an issue since the measurements do not include timestamps, making precise measurements difficult[23]. Several coping mechanisms have been used to mitigate this, notably *busypolling* (polling the counter for updates, significantly compromising overhead in terms of time and energy[75]), *supersampling* (lowering the sampling interval, increasing overhead and occasionally creating duplicates that need to be filtered[23]), or *high-frequency sampling* (lowering the sampling rate when the resulting data is still sufficient[76]). Another solution is to use a *low sampling frequency* to smooth out the relative error due to spikes, with the only drawback of a loss of temporal precision. At sampling rates slower than 50Hz, the relative error is less than 0.5%[24].
- **Non-atomic register updates:** RAPL register updates are non-atomic[23], meaning that the different RAPL values show a delay between individual updates. This may introduce errors when sampling multiple counters at a high sampling rate, making it possible to read both fresh and stale values of different counters.
- **Lower idle power accuracy:** When measuring an idling server, RAPL tends to be less accurate[8, 21].
- **Side-channel attacks:** While the update rate of RAPL is usually 1ms, it can get as low as 50 μ s for the PP0 domain (processor cores) on desktop processors[21]. This can be exploited to retrieve processed data in a side-channel attack (coined "Platypus")[21, 25].

To mitigate this issue while retaining RAPL functionality, Intel implements a filtering technique via the `ENERGY_FILTERING_ENABLE`[26, Table 2-2] entry or when *Software Guard Extension (SGX)* is activated in the BIOS. This filter adds random noise to the reported values (visualized in figure 2.4a). For the PP0 domain, this raises the temporal granularity to about 8ms. While this does not affect the average power consumption, point measurement power consumption can be affected. Figure 2.4 shows the effect of the filter, clearly indicating the loss of granularity resulting from its activation. In a 2022 article, Tamara[77] found a surprisingly higher mean with the filter activated and deemed filtered RAPL energy data unusable. In a more elaborate experiment in 2024, Schöne et al. did not encounter these inaccuracies anymore.

FIGURE 2.4: Observable loss of granularity caused by the activation of ENERGY_FILTERING_ENABLE[21]

2.4.2.4 RAPL Conclusions

The energy measurement accuracy of RAPL has significantly improved since its inception and provides a generally accepted way to measure system energy consumption. It is well-validated and accepted as the most accurate fine-granular energy measurement tool. Some known limitations have historically caused inaccuracies in developed measurement tools, but corrections for these limitations exist.

2.4.3 Graphical Processing Units (GPU)

In recent years, the utilization of GPUs in cloud computing environments has grown significantly, driven primarily by the increasing demand for high-performance computations in machine learning, artificial intelligence, and large-scale data processing[79]. Kubernetes now includes mechanisms for GPU provisioning, enabling containerized workloads to leverage GPU acceleration[80].

Although GPUs remain less common than traditional CPU-based workloads in typical Kubernetes clusters, their adoption is rapidly accelerating. Industry reports indicate that GPU usage in Kubernetes has seen a growth rate of nearly 58% year-over-year, outpacing general cloud computing growth rates[81]. This increase is largely attributed to ML workloads and real-time processing tasks that benefit from the parallel processing capabilities of GPUs[82]. Furthermore, hyperscalers have integrated GPU support directly into their managed Kubernetes services, reflecting the growing demand for GPU-powered workloads in containerized environments.

Despite this growth, GPU deployments are still not as pervasive as CPU-based workloads in Kubernetes-managed clusters. The primary focus of this thesis is on the

measurement and analysis of energy consumption in more common CPU- and memory-centric Kubernetes workloads. Nevertheless, due to the rising significance of GPUs, their energy measurement techniques and potential integration within Kubernetes environments are briefly examined.

Ultimately, the inclusion of GPU energy measurements remains outside the primary scope of this thesis but is acknowledged as an important area for future research. This structured exploration serves to highlight current limitations and opportunities for enhancing energy efficiency in Kubernetes-managed GPU workloads.

2.4.3.1 GPU Virtualization Technologies

Full GPU Virtualization Full GPU virtualization provides isolated instances of a single physical GPU to multiple virtual machines. This is achieved using technologies such as NVIDIA's *vGPU* or AMD's *MxGPU (Multiuser GPU)*. These technologies allow a VM to see a complete GPU, while the underlying hypervisor manages resource partitioning and scheduling[83, 84], either through partitioning or timeslicing. In a Kubernetes environment, full GPU virtualization is commonly utilized through:

- **vGPU on VMware or OpenStack:** Kubernetes clusters running on VMware vSphere or OpenStack can request vGPU instances as if they were physical GPUs. These instances are shared among containers while maintaining memory and compute isolation.
- **Device Plugin Integration:** NVIDIA, AMD, and Intel provide a Device Plugin for Kubernetes, enabling seamless GPU discovery and allocation across pods[80].

Multi-Instance GPU (MIG) Introduced with the NVIDIA A100 architecture, Multi-Instance GPU (MIG) allows a single GPU to be partitioned into up to seven independent instances, each with its own dedicated compute, memory, and cache resources[85]. Unlike traditional vGPU, MIG provides true hardware-level isolation, preventing noisy-neighbor effects and enabling finer resource allocation. MIG instances are exposed to Kubernetes as individual GPUs. For example, a single A100 GPU partitioned into seven MIG instances appears as seven separate GPU resources, each assignable to different containers. MIG-aware device plugins ensure proper scheduling and isolation. Hence, MIG technology is particularly useful for multi-tenant environments and supports finer granularity in resource allocation compared to traditional vGPU models.

GPU Passthrough GPU passthrough allows a physical GPU to be exclusively assigned to a single VM or container. Unlike virtualization, where resources are shared, passthrough dedicates the full GPU to one environment, offering near-native performance[86]. GPU passthrough is configured at the hypervisor level (e.g. KVM or VMware ESXi) and can be exposed to Kubernetes nodes. Pods scheduled on nodes with GPU passthrough access gain complete control of the GPU, enabling direct memory access and high-performance computation.

GPU virtualization technologies enable efficient multi-tenant use of GPU resources, enhancing performance and cost-effectiveness in cloud-native environments. For

the purposes of energy measurement, understanding these virtualization layers is essential for accurate per-container energy attribution.

2.4.3.2 GPU NVIDIA-NVML Energy Measurements and Validation

Modern GPUs are equipped with **built-in power sensors** that enable real-time energy measurement. For instance, NVIDIA GPUs expose power metrics through the *Nvidia System Management Interface (nvidia-smi)*, which reports instantaneous power draw, temperature, and memory usage[87]. This interface allows for programmatic access to GPU power consumption, making it a common choice for monitoring and energy profiling in both standalone and containerized environments[85].

In 2024, Yang et al. conducted a comprehensive study on the accuracy and reliability of NVIDIA's built-in power sensors, examining over 70 different models[27]. They concluded that previous research placed excessive trust in NVIDIA-NVML, overlooking the importance of measurement methodology. The study revealed several critical findings:

- **Sampling Limitations:** NVIDIA NVML offers the option to specify a sampling frequency in units of milliseconds. However, on certain models, such as the A100 and H100, power is sampled only around 25% of the time, introducing potential inaccuracies in total energy consumption estimations.
- **Transient Response Issues:** While measured power reacted instantly to a suddenly applied workload, NVIDIA-NVML would report values with a delay of several hundred milliseconds on some devices. Additionally, a slower rise (with linear growth) was observed, taking over a second to reach correct power figures in some instances. Generally, server-grade GPUs were shown to provide more instantaneous power measurements.
- **Measurement Inaccuracies:** The average error rate in reported power draw was found to be approximately 5%, deviating from NVIDIA's claimed fixed error margin of 5W. This error remained consistent when the GPU reached a constant power draw.
- **Averaging Effects:** Reported power consumption values are averaged over time, masking short-term fluctuations and potentially underreporting peak consumption.

To address these limitations, the study proposed best practices such as running multiple or longer iterations of workloads to average out sampling errors, introducing controlled phase shifts to capture different execution states, and applying data corrections to account for transient lags[27]. These adjustments reduced measurement errors by up to 65%, demonstrating the importance of refining raw sensor data for more accurate energy profiling.

2.4.3.3 Related Research

While most research has used NVIDIA-NVML to measure GPU power consumption, some research has focused on alternative measurement tools, usually to address issues similar to those stated by Yang et al. in the previous section. Specifically,

the following three tools were proposed to provide higher sampling rates to enable finer-grained power analysis.

AccelWattch In 2021, Pan et al. proposed *AccelWattch*[88], a configurable GPU power model that provides both a higher accuracy cycle-level power model and a way to measure constant and static power, utilizing any pure-software performance model, NVIDIA-NVML, or a combination of the two. Notably, their model is DVFS-, power-gating-, and divergence-aware. The resulting power model was validated against measured ground truth using an NVIDIA Volta GV100, yielding a MAPE error between $7.5 - 9.2 \pm 2.1\% - 3.1\%$, depending on the AccelWattch variant. The Volta model was later validated against Pascal TITAN X and Turing RTX 2060 architectures without retraining, achieving $11 \pm 3.8\%$ and $13 \pm 4.7\%$ MAPE, respectively. The authors conclude that AccelWattch can reliably predict power consumption of these specific GPU architectures. In the context of Kubernetes energy consumption, AccelWattch contributes a fine-grained temporal granularity.

FinGraV In 2024, Singhania et al. proposed *FinGraV*[89] (abbreviated from **Fine-Grain Visibility**), a fine-grained power measurement tool capable of sub-millisecond power profiling for GPU executions on an AMD MI300X GPU. They identified the following main challenges of high-resolution GPU power analysis (see figure 2.5a):

- **Low Sampling Frequency:** Standard GPU power loggers operate at intervals too coarse (tens of milliseconds) to capture the sub-millisecond executions of modern kernels.
- **CPU-GPU Time Synchronization:** Synchronizing power measurements with kernel start and end times is problematic due to the asynchronous nature of CPU-GPU communication.
- **Execution Time Variation:** Minor variations in memory allocation or access patterns lead to inconsistent kernel execution times, complicating time-based power profiling.
- **Power Variance Across Executions:** Repeated executions of the same kernel, or interleaved executions with other kernels, result in fluctuating power consumption, challenging consistent profiling.

FIGURE 2.5: FinGraV GPU power measurement challenges and strategies[89]

To overcome these challenges, FinGraV introduces several strategies (see figure 2.5b):

- **On-GPU Power Logger:** FinGraV leverages a high-resolution (1 ms) power logger, capturing the average of multiple instantaneous power readings.
- **High-Resolution Time Synchronization:** GPU timestamps are read from the CPU side before kernel execution, and synchronization is maintained throughout execution to correlate power samples with kernel events.
- **Execution Time Binning:** Kernel executions are grouped into "bins" based on empirical runtime ranges, enabling tighter power profiling while discarding outlier runs.
- **Power Profile Differentiation:** FinGraV distinguishes between Steady-State Execution (SSE) and Steady-State Power (SSP) profiles. SSP represents the stabilized power consumption after initial transients, providing the most accurate depiction of kernel power consumption.

The application of FinGraV to benchmarks reveals several critical observations: Kernel executions differ significantly between initial runs and steady-state, with deviations of up to 80%. Memory-bound kernels and compute-light kernels are found to be highly sensitive to the preceding kernel, impacting their power profile. Furthermore, the authors expose discrepancies in GPU power scaling relative to computational load, particularly for compute-light kernels.

FinGraV introduces promising concepts that could, in theory, enable more granular and accurate GPU power analysis in container-based GPU workloads. Its methodological approach addresses key challenges in sub-millisecond power measurement. However, its current implementation is tightly coupled with the AMD MI300X GPU,

relying on hardware-specific logging capabilities that are not universally available. While the underlying concepts may be extendable to other GPUs, achieving this is far from trivial, requiring significant adaptation and low-level access to power metrics that are often proprietary or limited by driver capabilities.

Consequently, FinGraV highlights both the challenges and potential solutions for fine-grained GPU power analysis but falls short of providing a general-purpose framework that could be easily integrated into Kubernetes energy measurement tools. It also underscores the broader issue that GPU energy consumption analysis remains relatively immature, with only vendor-specific tools like NVIDIA-NVML offering practical (but coarse) power metrics. This illustrates that while the methodology is theoretically sound, practical implementation across diverse GPU architectures remains a significant challenge.

PowerSensor3 *PowerSensor3*[9] is an open-source hardware tool introduced in 2025, designed to provide high-resolution power measurements for GPUs, SoC boards, PCIe devices, SSDs, and FPGAs. Unlike software-based power models or vendor-specific tools such as NVIDIA’s NVML, PowerSensor3 achieves significantly higher accuracy and granularity through direct voltage and current measurements at a sampling rate of up to 20 kHz. This fine temporal resolution allows it to capture transient power behaviors that are typically missed by software-based methods, which are constrained by lower sampling frequencies and indirect estimations. As expected for a purpose-built hardware solution, PowerSensor3 outperforms NVML in both precision and the ability to detect rapid changes in power consumption.

A particularly valuable feature of PowerSensor3 is its capability to monitor not only GPUs but also other critical components such as SoC boards, PCIe-connected accelerators, and storage devices like SSDs. For Kubernetes-based energy efficiency analysis, this would provide unprecedented visibility into the power usage of individual containers, extending monitoring beyond the CPU and GPU to the broader spectrum of peripherals that contribute to overall energy consumption. Such granularity could enhance resource scheduling and energy optimization in containerized environments.

However, while its technical benefits are evident, the practical deployment of dedicated hardware sensors like PowerSensor3 at scale remains both complex and expensive. Integrating such devices across large Kubernetes clusters would require substantial investment in hardware and reconfiguration of infrastructure, making wide adoption unlikely outside of specialized research environments. Consequently, PowerSensor3 and other hardware-dependent methods are not considered in the scope of this thesis. Furthermore, the very recent introduction of PowerSensor3 in 2025 highlights the ongoing challenges of accurate energy monitoring through software alone, reflecting the current gap in reliable, scalable, software-based power measurement solutions.

2.4.3.4 GPU Limitations in Kubernetes Context

The analysis of GPU power consumption has revealed promising research efforts aimed at achieving fine-grained power visibility and energy optimization. Tools such as FinGraV and PowerSensor3 demonstrate that significant strides are being

made in capturing detailed power metrics with high temporal resolution and sub-component granularity. FinGraV addresses the complexities of short-lived GPU kernel executions through innovative profiling methodologies, while PowerSensor3 delivers hardware-level accuracy for GPUs, SoC boards, and various PCIe-connected peripherals. These solutions underscore the potential for more refined power monitoring in high-performance GPU workloads.

However, the current state of GPU energy consumption measurement presents significant challenges for scalable, container-based energy tracking in Kubernetes environments. Research tools like FinGraV and PowerSensor3, while technically robust, are either hardware-dependent or too tightly coupled to specific architectures (such as AMD's MI300X in the case of FinGraV). Hardware-based solutions like PowerSensor3, though highly accurate, are impractical for widespread deployment due to cost and scalability concerns. Meanwhile, software-based vendor solutions such as NVIDIA's NVML are far more accessible but suffer from limitations in temporal granularity and measurement accuracy. These tools offer convenient integration and broad support across data center infrastructures but struggle with capturing rapid transients in power consumption, which are crucial for real-time container energy attribution.

In the context of this thesis, GPU energy consumption is acknowledged as an important yet currently impractical aspect of container energy measurement. The relative immaturity of fine-grained, scalable monitoring solutions for GPUs, combined with the relatively small role of GPUs in Kubernetes clusters, justifies this exclusion. Although the utilization of GPU accelerators in Kubernetes environments is expected to grow, current measurement methods do not yet support the level of precision and scalability required for effective implementation. As such, this thesis will focus on more readily measurable server components, with the understanding that future advancements in GPU power analysis may enable their integration into Kubernetes-based energy efficiency strategies.

2.4.4 Storage Devices

Various studies have investigated the power consumption of storage devices. In 2008, Hylick et al.[90] investigated real-time HDD energy consumption and found significant differences in power consumption between standby, idle, and active power states. Cho et al.[38] proposed various energy estimation models for SSDs after measuring and comparing the energy consumption of different models. The most notable model-based energy consumption estimation mechanisms are presented in § 2.5.4.

In contrast to CPU or GPU components, storage devices (HDD, SSD, or NVMe drives) cannot make use of physical power sensors. While a BMC-measurement-based solution would technically be feasible, real-world implementation is impractical: while a BMC might be able to measure the power supply to a storage device, it typically is not exposed through IPMI or Redfish. Such measurements would further be complicated by the use of backplane devices, making measurements for individual devices impossible. For these reasons, storage device energy consumption is typically modelled, not measured (see § 2.5.4).

While storage devices don't expose any energy-consumption-specific metrics, many other related metrics are available (and can be used for modeling approaches):

- NVMe-`cli`[37] exposes many metrics of NVMe drives, including the maximum power draw for each power state (including idle power), the number of power states supported, the current power state and temperature, and others.
- `smartctl`[36] exposes metrics of the *SMART (Self-Monitoring, Analysis and Reporting Technology)* functionality implemented in many modern storage drives. While these metrics are vendor-specific, they often include temperature, throughput, and other indicators. Often, HDD speed is exposed. Notably, *SMART* metrics are typically more focused on lifecycle information such as power-on hours, wear indicators, and others.
- Many other performance metrics are exposed by various tools such as `iostat`, `sar`, `/proc/diskstats`, and `blkstat`, such as read/write IOPS, throughput, queue length, latency, utilization, and others. Additional information (such as the interface) is also exposed.

2.4.5 Network Devices and Other PCIe Devices

Peripherals like the Network Interface Card (NIC) are almost always connected via PCIe. As such, many cards support device power states[44] as specified by the PCIe specifications. Notably, not all NICs support all (or any) power states. These device states allow the server and device to negotiate a power state for the device, which typically means choosing a trade-off between power consumption and wake-up latency. For devices, PCIe specifies the following device states:

- D0 state (Fully on)
- D1 and D2 states (Intermediate power states)
- D3 state (Off state), with the distinction between D3hot and D3cold

Unfortunately, device power states are not in any way related to physical power specifications: while a specific power state might be useful for simple deductions (e.g. if a device is idling or active), no power figures can be deduced. In the event that a device's idle or maximum power is known, power states might potentially be used for a first estimation (i.e., an idling device is unlikely to consume its specified maximum power, and vice versa), but since a device's power characteristics cannot be reliably estimated (especially beyond just NICs), device power states cannot be used to reliably estimate device power consumption. An attempt at the estimation of NIC power consumption is covered in § 2.5.5.

2.5 Model-Based Estimation Techniques

In the absence of actual power data, power consumption models can be formulated that map variables (such as CPU or memory utilization) related to a server's state to its power consumption.

Due to the strong correlation between CPU utilization and server power, a great number of models use CPU metrics as the only indicator of server power. Fan et al.[45] proposed a linear interpolation between idle power and full power, which

they further refined into a non-linear form, with a parameter γ to be fitted to minimize mean square error. Similar research was done to further reduce error by introducing more complex non-linear models, such as Hsu and Poole[46], who studied the SPECpower_ssj2008 dataset of systems released between December 2007 and August 2010, and suggested the adaptation of two non-linear terms:

$$P_{\text{server}} = \alpha_0 + \alpha_1 u_{\text{cpu}} + \alpha_2 (u_{\text{cpu}})^{\gamma_0} + \alpha_3 (1 - u_{\text{cpu}})^{\gamma_1} \quad (2.3)$$

The division of server power consumption into idle (generally static) and dynamic power (modeled with many different methods throughout related research) has historically been a popular suggestion[91]. Other broadly similar attempts to model server energy consumption based on only a few variables exist, such as modeling server consumption based on CPU frequency[92].

2.5.1 Component-Level Power Models

While models like the ones listed above might work well when custom-fitted to specific, multi-purpose servers, they have since been surpassed by the more common approach of modelling server power as an assembly of its components, as Song et al.[47] propose:

$$P_{\text{server}} = P_{\text{cpu}} + P_{\text{memory}} + P_{\text{disk}} + P_{\text{NIC}} + C \quad (2.4)$$

where C denotes the server's base power, which includes the power consumption of other components (regarded as static). This approach can easily be extended to include various other components such as GPUs, FPGAs, or other connected devices.

2.5.1.1 Advantages and Disadvantages of Component-Level Power Models

A component-based approach to modeling server power consumption offers increased granularity and adaptability across a diverse range of server architectures. Modern data centers deploy heterogeneous hardware configurations optimized for specific workloads, such as CPU-intensive computing nodes, GPU-accelerated servers for machine learning, or memory-rich systems for in-memory databases. These configurations lead to vastly different power distribution profiles across components[93]. By modeling the energy consumption of individual components, it becomes possible to reflect these structural differences more accurately. Additionally, such models can reveal energy characteristics that would be obscured in aggregate metrics (for instance, a workload that imposes significant stress on storage devices without engaging the CPU may go undetected in simplistic, CPU-centric models). Finally, component-level analysis enables more precise evaluation of energy optimization techniques: the impact of mechanisms like dynamic voltage and frequency scaling (DVFS) or idle power states can be assessed not just in isolation but in terms of their contribution to overall server efficiency.

Despite offering finer granularity, component-based power modeling faces several inherent challenges. While servers are composed of individual components, they function as tightly integrated systems in which no component operates in isolation. The power consumption of one subsystem often depends on the behavior of others (for example, memory access patterns can influence CPU power states,

and I/O activity may trigger CPU wake-ups or increased cache usage). These inter-component interactions are difficult to capture accurately and are frequently overlooked in component-level models[2], leading to potentially misleading or incomplete estimations. Furthermore, the development of detailed and accurate models for each component is significantly more complex than holistic server-level modeling. Such models often require extensive empirical data, sophisticated estimation techniques, and continuous updates to remain valid across hardware generations. This not only increases the research burden but also demands a higher level of expertise for interpretation and practical application compared to simpler, utilization-based models.

2.5.2 CPU

Existing CPU power models generally model CPU power as a combination of other, existing power figures. Fan et al.[45] propose a linear interpolation between idle power and full power based on CPU utilization. Basmaidian et al.[94] observe that individual cores in a multi-core CPU can be modeled as individual cores, in addition to an overall CPU idle consumption. Non-linear models are also widely adopted, with Lou et al.[95] proposing a polynomial model as a univariate function of CPU utilization. Other models include individual CPU components[96, 97] for more fidelity.

While these models may be helpful to examine the dynamics of CPU power consumption in relation to different inputs, they are not helpful in finding CPU power consumption of an unknown CPU, i.e., without previously known idle or maximum power consumption. The existence of a model capable of accurately estimating CPU power consumption based solely on generalizable input factors (such as utilization or frequency) is questionable due to the great variance in architectures and technologies, as well as technological progress. Unsurprisingly, the author of this thesis was not able to find a model to estimate CPU power consumption.

2.5.3 Memory

Many memory power models have been proposed in the literature, many of them with an idle and a dynamic component of memory power consumption. While the idle power consumption is generally assumed to be known, dynamic memory power consumption has been modeled to depend on memory usage[98] or memory accesses[99], the number of cache misses[100], memory state[94], or other factors. Similar to the CPU models presented in the previous section, these models do not propose generalizable models able to predict memory consumption in situations where idle or maximum memory consumption is not previously known, instead focusing on examining power consumption dynamics. The same objections preventing generalizable CPU models apply to memory models as well, namely great variety, specialization, and technological progress. As a result, no model-based approaches exist that are capable of accurately estimating memory power consumption based solely on performance metrics.

2.5.4 Storage Devices

2.5.4.1 Generalization-Based Estimation

There is an urgent need in the storage industry for research into the area of workload-dependent power estimation[101]. Estimating the energy consumption of a storage device is challenging, especially due to the great variation between different devices. Some of these model variables can be determined on a running server system (e.g. device type, I/O operation type, access pattern, workload intensity, state, and more), while other variables are unknown to the server (e.g. Flash Transition Layer and flash factor, NAND organization, garbage collection, and more). A large storage device market has led to a high variation in devices with sometimes drastically different target uses (e.g. low-latency storage devices, high-concurrency storage devices, low-power storage devices).

Storage controllers further complicate the energy consumption estimation of storage devices by introducing an additional layer of abstraction between the operating system and the physical storage hardware. Their internal operations consume energy independently of the actual read/write workload observed by the host system. This makes it difficult to directly correlate application-level I/O activity with actual device-level power usage. Moreover, in many server configurations, multiple drives are managed behind a single controller, obscuring per-device energy attribution and introducing variability that model-based estimations often cannot accurately capture.

Scope Clarification In this thesis, only storage devices physically installed in the server are considered for power estimation. This includes devices such as HDDs, SSDs, and NVMe drives directly attached to the server. Dedicated external storage systems such as Storage Area Networks (SAN) or Network-Attached Storage (NAS) are not within the scope of this analysis. While such systems are important in data center environments, their energy consumption is not attributable at the granularity required for the workload-level estimation pursued in this thesis.

As a result, research into storage device energy consumption measurement that is generally applicable to all devices has been limited. For practical applications, generalizations are often used, such as the following tables 2.3a to 2.3d. While these approximations cannot be used in the context of this thesis, they may serve as an initial guideline.

HDD Type	Read/Write Power (W)	Idle Power (W)	Standby Power (W)
HDD (2.5" SATA)	1.5 – 3.0	0.5 – 1.2	0.1 – 0.3
HDD (3.5" SATA)	6 – 12	4 – 8	0.5 – 2.0
HDD (Enterprise)	7 – 15	5 – 10	0.5 – 2.5

(A) Typical HDD power consumption[102]

HDD Type	Read/Write Power (W)	Idle Power (W)	Standby Power (W)
5400 RPM HDD	6 – 9	4 – 6	0.5 – 1.5
7200 RPM HDD	8 – 12	6 – 8	0.6 – 1.8
10,000+ RPM HDD	10 – 16	8 – 12	1.0 – 2.5

(B) Common HDD RPM power consumption[102]

SSD Type	Read Power (W)	Write Power (W)	Idle Power (W)
2.5" SATA	4.5 – 8	4.5 – 8	0.30 – 2
mSATA	1 – 5	4 – 8	0.20 – 2
M.2 SATA	2.5 – 6	4 – 9	0.40 – 2

(C) Typical SATA SSD power consumption[103]

NVMe Type	Read/Write Power (W)	Peak Power (W)	Standby Power (W)
M.2 NVMe PCIe 3.0	3 – 5	6 – 9	0.4 – 1.5
M.2 NVMe PCIe 4.0	5 – 7	8 – 12	0.5 – 2
M.2 NVMe PCIe 5.0	8 – 12	12 – 18	0.8 – 3

(D) Typical NVMe SSD power consumption[103]

TABLE 2.3: Power consumption for various storage device types.

Apart from simple estimations like those shown in tables 2.3a to 2.3d, a few works have focused on the energy consumption of individual storage devices. In 2015, Cho et al. developed Energysim[38], an SSD energy modeling framework advancing the understanding of component-level (i.e., the subcomponents of a storage device) energy consumption in storage devices. Its validation against real-world SSD measurements using an Intel X25-M yielded a less than 8% error. The work underscores the difficulty of modeling storage energy accurately due to high variability across architectures and workloads. Unfortunately, Energysim uses many model parameters such as NAND organization, idle and active current consumption, and as a result cannot be generalized to other storage devices where these are unknown.

In 2014, Li and Long[39] presented a workload-aware modeling framework to estimate the energy consumption of storage systems, challenging the assumption that SSDs are inherently more energy-efficient than HDDs. By classifying I/O workloads into capability workloads (performance-driven) and capacity workloads (storage size-driven), they developed mathematical models that account for the number of devices needed, workload execution time, and device power states (active, idle, standby). Their validation, based on empirical measurements using Seagate HDDs and a Samsung SSD, shows that SSDs are generally more efficient for high-performance workloads, while HDDs can outperform SSDs in archival or low-access

scenarios, particularly when effective power management (e.g. spin-down) is employed. Unfortunately, similar to the research by Cho et al., the presented models make use of various non-generalizable variables, most notably a device's idle, standby, and busy power consumption. In the context of this thesis, these are unknown, and the presented model consequently cannot be applied.

2.5.4.2 GSPN Modeling for Hybrid Storage Systems (Active Power States)

In 2022, Borba et al.[40] proposed a number of models based on generalized stochastic Petri nets (GSPN) for performance and energy consumption evaluation of individual and hybrid (HDD + SSD) storage systems. GSPN is a suitable formalism for storage system design as, unlike queueing network models, synchronization, resource sharing, and conflicts are naturally represented. Also, the phase approximation technique may be applied for modeling non-exponential activities, and events with zero delays (e.g. workload selection) may adopt immediate transitions.

The authors propose a single-storage model (either for a single storage device or a hybrid system as a blackbox) and a multiple-storage model.

The hybrid storage power consumption model proposed by Borba is parameterized by I/O type (read/write), access pattern (sequential/random), object size (4KB, 1MB), and thread concurrency. The model explicitly incorporates power consumption per operation (e.g. random-read-4KB on SSD).

The following notation is adopted:

- $E\{\#p\}$ represents the mean value of the inner expression, in which $\#p$ denotes the number of tokens in place.
- $W(T)$ represents the firing rate associated with transition T .
- $\eta : T_{\text{imm}} \rightarrow [0, 1]$ maps each immediate transition ($t \in T_{\text{imm}}$) to a normalized weight. Weights represent the transition firing probability in a conflict set.
- $p\text{Requests}(N)$ denotes the amount of concurrent requests from simultaneous clients (workers).

Single-device storage energy consumption is estimated as follows:

$$\begin{aligned} EP_w = & \kappa \cdot (EP_{w1} \cdot \alpha \cdot \beta + EP_{w2} \cdot (1 - \alpha) \cdot \beta \\ & + EP_{w3} \cdot \alpha \cdot (1 - \beta) + EP_{w4} \cdot (1 - \alpha) \cdot (1 - \beta)) \end{aligned} \quad (2.5)$$

$$\begin{aligned} EP_r = & (1 - \kappa) \cdot (EP_{r5} \cdot \alpha \cdot \beta + EP_{r6} \cdot (1 - \alpha) \cdot \beta \\ & + EP_{r7} \cdot \alpha \cdot (1 - \beta) + EP_{r8} \cdot (1 - \alpha) \cdot (1 - \beta)) \end{aligned} \quad (2.6)$$

$$EC = (EP_w + EP_r) \cdot TH \cdot \text{time} \quad (2.7)$$

where EP_w and EP_r are the mean power consumption for a read (r) or write (w) operation, which is estimated using the mean power of each workload feature. For instance, EP_{w1} denotes the power of a write operation (w) using random access (α) and a small object (β). System throughput (i.e., IOPS) is estimated as $TH = E\{\#p_{\text{Ack}}\} \times W(t_{\text{Communicating}})$. For the single-device model, the following weights are taken into

account: $\eta(t_{\text{Write}}) = \kappa$; $\eta(t_{\text{Read}}) = 1 - \kappa$; $\eta(t_{\text{Random}}) = \alpha$; $\eta(t_{\text{Sequential}}) = 1 - \alpha$; $\eta(t_{\text{Small}}) = \beta$; and $\eta(t_{\text{Large}}) = 1 - \beta$.

The marking of place $pResource(R)$ (for both read or write activity) may denote the adopted technology. For instance, for traditional SSDs (SATA interface), the marking place $pResource$ is 1, as only one operation at a time is carried out. Concerning SSDs-NVMe, $pResource$ assumes the number of threads concurrently processing I/O requests (generally 8).

The proposed multi-storage model expands the model for multiple devices:

$$EC_h = \left(\sum_{d=0}^n \eta(tForward_d) \cdot EP_d \right) \cdot TH_h \cdot \text{time} \quad (2.8)$$

where the immediate transitions $tForward_d$ denote a request redirection to storage d .

Validation The model proposed by Borba et al. was validated using controlled experiments with the Fio benchmarking tool, which generated synthetic I/O workloads to measure and correlate storage system performance and energy consumption across varying request sizes, access patterns, and read/write ratios. Model estimates consistently fell within the 95% confidence intervals of observed system metrics. This statistical consistency indicates that the model's predictions are not significantly different from real-world values, supporting its applicability for performance and energy analysis in large-scale storage systems.

Limitations The authors acknowledge that a large number of devices significantly increases modeling complexity due to state space size explosion and recommend simulation as a viable workaround. Additionally, the authors acknowledge their focus on active energy states (not idle, standby states, or state transitions), treating them as delays between requests.

In a running server system, this approach could be adapted to create an accurate and fine-grained energy consumption estimation of a read/write workload on specific storage devices, albeit with limitations:

- Instead of needing to be estimated, (device-specific) throughput (TH) can be measured.
- An initial calibration run is necessary to experimentally determine the respective device-specific variables.
- In a multi-storage device server, the resulting state explosion may lead to significant calculation overhead, resulting also in higher energy consumption of the measurement itself.
- Instead of modelling transitions to a storage device as a function (as done in $\eta(tForward_d)$), device usage would actively need to be measured, which would essentially transform the multi-storage model into a simple addition of single-storage models. This would drastically reduce the number of total states, making calculations less demanding.

- Due to the authors not considering idle and standby states, a small, constant idle power consumption would need to be added to the model. This is especially important for accurate storage device power consumption modeling on idling or overprovisioned servers.

2.5.5 Network devices

Estimating the total power consumption of a network infrastructure requires a clear definition of system boundaries. Since most server clusters operate within larger, interconnected systems, a full assessment of network energy consumption (such as for CO₂ footprint calculations) is generally infeasible. This thesis limits the system boundary to the server itself, considering only internal network components, primarily the Network Interface Card (NIC). While this allows detailed modeling of NIC power usage, it excludes broader network activity, such as inter-node communication in multi-node clusters.

Although the overall energy consumption of a data center network could be estimated by including access, aggregation, and core switches, attributing this consumption to specific workloads remains highly challenging. This chapter therefore focuses on model-based methods for estimating NIC-level power as a proxy for server-side network energy usage.

2.5.5.1 NIC power consumption characteristics

While extensive research has analyzed the power consumption of network equipment like switches, routers, or gateways, NICs (especially non-wireless NICs) have not received as much attention. While several methods exist that modern NICs use to save power (e.g. PCIe Link power states and D-states, *Active State Power Management (ASPM)*, or *Energy Efficient Ethernet (EEE)*), there are no widely available mechanisms for fine-grained NIC power consumption estimation. As a consequence, NIC power can only be approximated based on the few available metrics.

Sohan et al.[41] measured and compared the power consumption of six 10 Gbps and four multiport 1 Gbps NICs at a fine-grained level. While they do not provide a method to estimate NIC energy consumption, they noted significant variation in power consumption between different NICs. Unfortunately, it cannot be ruled out that some results are cherry-picked: Solarflare NICs tend to dominate the introduced metrics, and a communications spokesperson is prominently credited with contact information. Regardless, some findings are consistent across manufacturers and align with other literature sources[104]. While these findings cannot directly contribute to a potential NIC power consumption estimation approach, they are relevant to understanding underlying mechanisms and assessing the relative importance of the NIC compared to other server components.

- **Idle Power**

- The measured NICs showed power consumption between 5–20W.
- Link connection status had little effect on idle energy consumption.
- Physical media influenced power consumption: CX4 models had the lowest power consumption due to the simple design of the CX4 interconnect.

This was followed by fiber models. Finally, Base-T models consumed significantly more power due to the signal processing components in the card.

- **Active Power**

- There was very little difference in the power usage of an active NIC compared to an idle one. For all measured NICs, the difference in power usage was less than 1W.
- Throughput performance varied widely, and no correlation between power usage and performance was observed.
- Power consumption increased in correlation with the number of ports.

In 2012, Basmadjian et al.[42] modeled a NIC by separating NIC power consumption into idle mode and dynamic mode (as they did for their CPU and RAM models). If $P_{NIC_{idle}}$ is the power of the idle interface and $P_{NIC_{dynamic}}$ is the power when active, the total NIC energy consumption is given by:

$$E_{NIC} = P_{NIC_{idle}} T_{idle} + P_{NIC_{dynamic}} T_{dynamic} \quad (2.9)$$

where T_{idle} and $T_{dynamic}$ are the total idle and dynamic times, respectively. Consequently, the average power during period T is given by:

$$P_{NIC} = \frac{(T - T_{dynamic})P_{NIC_{idle}} + P_{NIC_{dynamic}} T_{dynamic}}{T} \quad (2.10)$$

$$= P_{NIC_{idle}} + (P_{NIC_{dynamic}} - P_{NIC_{idle}})\rho \quad (2.11)$$

where $\rho = \frac{T_{dynamic}}{T}$ is the channel utilization. While this formula is only helpful when NIC idle and max power consumption are already known, it shows that NIC power consumption is assumed to rise linearly with channel utilization.

Arjona Aroca et al.[48] modeled NIC efficiency based on their previous measurements. They found that NIC efficiencies for both sending and receiving are almost linear with the transfer rate and deduced a linear dependency on the network throughput.

In 2016, De Maio et al.[105] proposed a network energy consumption model for node-to-node transfers to estimate the total energy consumption required for virtual machine migration. Unfortunately, their model does not specifically handle NIC energy consumption, opting to model the entire node's energy consumption instead.

Another approach is presented by Dargie and Wen[106], who used stochastic modeling to examine the relationship between the utilization of a NIC and its power consumption, expressing these quantities as random variables or processes. They used curve fitting to determine the relationship between utilization and measured energy consumption of their specific NIC, after creating a dataset using a SPECpower benchmark. They assumed a uniformly distributed bandwidth utilization in the interval [0,125] MBps. Interestingly, their model showed only a slight effect of utilization on the predicted power consumption, mirroring the findings of Sohan et al.

The most recent NIC power model was proposed by Baneshi et al.[43] in 2024, analyzing per-application energy consumption. The authors noted that NIC idle power consumption may contribute up to 90% of the total NIC energy consumption. They proposed the following model for per-application NIC power consumption:

$$E_{\text{active}} = \sum_i \left(BW_i \cdot T_{\text{interval}} \cdot \frac{P_{\text{max}} - P_{\text{idle}}}{BW_{\text{aggregated}}} \right) \quad (2.12)$$

$$E_{\text{idle}} = \sum_i \left(BW_i \cdot T_{\text{interval}} \cdot \frac{P_{\text{idle}}}{BW_{\text{used}}} \right) \quad (2.13)$$

where BW_i is the bandwidth of application i , $BW_{\text{aggregated}}$ is the aggregate bandwidth of both the uplink and downlink of the NIC, and BW_{used} is the used bandwidth of links (uplinks, downlinks, or both). The authors combined these formulae with power figures of their specific use case (total network power consumption in a fog computing scenario), which unfortunately are not applicable in the context of this thesis. Regardless, while these formulae cannot be used to estimate the maximum and idle NIC power, they can be applied irrespective of server specifications if idle and maximum NIC power consumption are known.

In contrast to the formulae presented by Basmadjian and Arjona Aroca, these formulae not only account for time intervals but also bandwidth used. As a result, the formulae presented by Baneshi et al. represent the current best approach to estimate NIC power consumption, even though this estimation still requires an initial guess of the idle and maximum power consumption. The author of this thesis is not aware of a more detailed formula currently available. A generalizable formula for estimating overall NIC power consumption is unlikely to exist due to the vast variety of NICs and the significant differences between manufacturers (as found by Sohan et al.).

2.5.6 Other devices

While much of the research on server energy consumption focuses on primary components such as the CPU, memory, storage, and network interfaces, a complete energy model must also account for additional hardware subsystems. These include the motherboard, power supply unit (PSU), system fans, and potentially other auxiliary devices. Though their individual energy consumption may appear minor compared to high-performance components, they collectively contribute a non-negligible share to the overall server power draw.

Despite their importance, these secondary components have received limited attention in energy modeling literature. In most cases, they are either omitted or treated as part of the residual power not attributable to the main computational subsystems.

The motherboard, for instance, includes voltage regulators, chipset logic, and peripheral interfaces. While these components may not be individually monitored, the Baseboard Management Controller (BMC) (see § 2.3.2.1) may expose aggregated power telemetry via vendor-specific sensors or interfaces like IPMI or Redfish. However, this level of detail varies greatly across hardware platforms and is seldom fine-grained enough for component-level attribution.

2.5.6.1 PSU

The power supply unit (PSU) is another often-overlooked consumer. When modeling the power usage of a PSU itself (distinct from the power it delivers to other components), the key factor is its conversion efficiency. PSUs consume more power than they deliver due to losses during AC–DC transformation and voltage regulation. According to Basmadjian et al.[42], the power consumed by the PSU can be approximated for various scenarios:

If the monitoring system provides information at the PSU level, its power consumption is given by

$$P_{PSU} = \frac{measuredPower \cdot (100 - e)}{100} \quad (2.14)$$

where e is the efficiency of the PSU.

If the monitoring system provides information at the server level, the power consumption of any of the n PSUs is given by the following formula, assuming that measured power is evenly distributed among PSUs:

$$P_{PSU} = \frac{\frac{measuredPower}{n} \cdot (100 - e)}{100} \quad (2.15)$$

If the monitoring system does not provide PSU power consumption, it can be deduced by

$$P_{PSU} = \frac{P_{Mainboard} + P_{Fans}}{n \cdot e} \cdot 100 - \frac{P_{Mainboard} + P_{Fans}}{n} \quad (2.16)$$

2.5.6.2 Fans

Cooling systems, particularly fans, also represent a meaningful share of the total energy budget. Most servers employ multiple fans controlled via Pulse-Width Modulation (PWM). While the BMC or operating system tools (e.g. `lm-sensors`) often report fan RPM or PWM duty cycle, actual fan power consumption is rarely exposed directly. Furthermore, RPM alone is insufficient to estimate power accurately, as fan power depends on physical factors such as the fan diameter, pressure increase, or air flow delivered[42]:

$$P_{Fan} = d_p \cdot q = \frac{F}{A} \cdot \frac{V}{t} = \frac{F \cdot d}{t} \quad (2.17)$$

where d_p denotes total pressure increase of the fan (Pa or N/m²), q denotes the air volume flow (m³/s), F denotes force (N), A denotes fan area (m²), V denotes volume (m³), and t denotes time (seconds).

Based on observations, F is proportional to the square of RPM . This can be combined with formula 2.17:

$$P_{Fan} = \frac{c \cdot RPM^2 \cdot d}{3600} \quad (2.18)$$

where for each individual fan, $c = \frac{3600 \cdot P_{Max}}{RPM_{Max}^2 \cdot d}$ remains constant.

Unfortunately, with the wide variety of fans in servers (especially with fan size restrictions due to server heights), these formulae are only helpful when paired with more detailed information on fan characteristics like maximum RPM and power.

While these can more reasonably be assumed, this remains a rough estimation at best.

2.5.6.3 Attribution of secondary component power consumption to individual workloads

Despite these measurement limitations, estimating the energy consumption of secondary components is often less critical for attributing energy to workloads. This is because components like fans, mainboards, and PSUs primarily support the operation of primary subsystems. Their power consumption scales with the activity level of CPU, memory, disk, and networking devices: more computation leads to higher heat dissipation, increased power delivery, and thus greater fan and PSU activity.

Consequently, if the total server power consumption is known (for example, via wall power monitoring or BMC/Redfish readings) the residual power (i.e., total power minus the sum of measured CPU, RAM, disk, and network power) can be reasonably attributed to power delivery and thermal management subsystems. This residual can then be proportionally distributed among active workloads based on the power consumption of the primary components they utilize. In this context, fine-grained modeling of secondary components becomes unnecessary for workload attribution, as their energy use correlates closely with that of the primary subsystems they support.

2.5.7 Issues with model-based power estimation techniques

This thesis pursues two inherently conflicting objectives: achieving high-resolution, accurate energy consumption measurements while simultaneously developing a solution that remains broadly applicable across heterogeneous server environments without requiring extensive manual calibration or the manual input of complex device-specific information. Striking a balance between these goals is particularly challenging in the context of model-based energy estimation for devices that do not expose power telemetry data. Due to the wide variability among devices for a variety of factors, energy consumption models must necessarily abstract away much of the underlying complexity. Developing a model that is simultaneously fine-grained, highly accurate, and universally applicable across different technologies is, in practice, an unattainable goal.

As a result, any model integrated into a general-purpose energy estimation framework must err on the side of relative simplicity to preserve generality. While this approach diminishes the precision of device-specific energy attribution, it remains valuable for broader optimization tasks. For instance, autoscaling mechanisms, load balancers, and schedulers can still benefit significantly from approximate energy profiles. Likewise, cluster administrators aiming to improve energy efficiency holistically, or developers seeking to optimize their workloads, can gain useful directional insights even from coarse-grained models.

However, this simplicity imposes significant limitations for use cases that require device-specific energy optimization. General-purpose models are ill-suited for evaluating the energy efficiency of different device types, testing firmware-level adjustments, or validating the impact of power-saving features such as low-power states. In such scenarios, the model's abstraction may not just be insufficient, but actively misleading.

In the context of this thesis, this limitation is considered acceptable. The overarching objective is to facilitate scalable and portable energy estimation mechanisms for containerized environments, not to provide a diagnostic tool for hardware-level energy analysis. Nonetheless, this constraint should be kept in mind when interpreting the results and assessing their suitability for device-centric evaluation tasks.

2.6 Power Modeling based on Machine Learning Algorithms

In a taxonomy of power consumption modeling approaches, Lin et al.[2] analyze various machine learning-based power models in current literature, categorizing them into supervised, unsupervised, and reinforcement learning. A detailed reiteration of this taxonomy (as well as a methodological overview of machine learning and neural networks) is omitted here.

In the context of this thesis, machine learning-based approaches are not considered for the following reasons:

- The author was unable to identify a promising and reliable approach that is sufficiently generalizable to function across a wide range of server configurations. Likewise, no component-level models were found that met these criteria. While it is certainly possible to train machine learning models to estimate energy consumption for specific server setups with high accuracy, the aim of this thesis is to provide generalizable estimation methods applicable to varied systems.
- Machine learning fundamentally relies on large datasets that are both highly accurate and granular, ideally matching the quality expectations of the resulting model. As discussed in previous sections, such high-quality training data is rarely available in the domain of fine-grained power measurement. When such datasets do exist, they typically reflect highly specific hardware and workload configurations, making them unsuitable for generalization. Although it would be theoretically possible to generate a large dataset by systematically benchmarking thousands of CPUs, memory modules, GPUs, storage, and network devices across millions of configurations, such an undertaking is not practically feasible. Furthermore, any such dataset would require ongoing expansion to remain representative of new hardware generations.
- Finally, many of the technical implementation details underlying key telemetry features remain proprietary or undocumented. A notable example is the RAPL interface, whose internal workings are not publicly disclosed. At the same time, existing RAPL metrics already offer abstracted energy readings suitable for direct integration into power estimation tools, eliminating the need for an intermediate machine learning-based step.

In theory, machine learning-based power estimation models hold significant promise and may one day be realized. Such models could leverage complex, nonlinear relationships between hardware components and workloads, relationships that are inherently difficult or even impossible to capture through traditional analytical models. The predictive and adaptive capabilities of machine learning offer the potential for highly accurate, fine-grained estimations across a broad range of configurations. However, as of today, the development of such a comprehensive and generalizable

model remains out of reach. Realizing this vision would require extensive collaboration between original equipment manufacturers, cloud providers, data center operators, and research institutions to generate, standardize, and share high-quality telemetry data across diverse hardware and workload scenarios. Given the role of cloud computing in the current economic landscape, where proprietary knowledge and performance optimization constitute a competitive advantage at the corporate, national, and geopolitical levels, such broad cooperation appears unlikely. Consequently, machine learning remains a promising but currently impractical direction for universal server power modeling.

2.7 Component-specific summaries

This section offers practical guidelines for measuring or estimating the energy consumption of individual hardware components. While earlier chapters focused on theory and research, the focus here is on implementation: what works best, what challenges to expect, and how to improve accuracy with minimal effort. For each component, the most accurate method is highlighted, along with alternatives and fallback options. Simple improvements like entering datasheet values or running calibration workloads are discussed where relevant.

2.7.1 CPU

The most accurate and widely adopted method for measuring CPU energy consumption is Intel’s RAPL interface. It offers high temporal resolution, low overhead, and requires no external hardware. Among the available interfaces, `perf-events` is generally recommended due to its balance between usability, performance, and access control. The `powercap` interface offers simpler integration via `sysfs`, though with some limitations in domain structure and overflow handling. MSR access is discouraged due to complexity and privilege requirements. eBPF-based methods are powerful and used in advanced tools, but introduce high development complexity, kernel dependency, and lower portability.

On AMD systems, the `amd_energy` driver offers a RAPL-compatible interface, but it exposes fewer domains (e.g. no DRAM) and is generally less feature-rich than Intel’s implementation.

Despite some limitations (such as non-atomic register updates, idle power inaccuracies, and the absence of timestamps), RAPL is considered sufficiently accurate for both research and production use. Its drawbacks can often be mitigated through careful sampling strategies (e.g. overflow-safe polling intervals, timestamp alignment) and correction techniques for overflow and measurement jitter.

ACPI, while historically relevant, does not expose real-time power data and is unsuitable for precise energy measurement. Although some theoretical estimation based on P-states is possible, it is coarse-grained and impractical for modern CPUs with dynamic frequency scaling.

If RAPL is unavailable, statistical models based on utilization, frequency, and other metrics may be used. However, these require prior calibration or hardware-specific profiling. Without access to idle or peak power values, such models become highly unreliable due to architectural variability. In such cases, estimation accuracy can be

modestly improved by inserting static power values from processor datasheets or using fixed coefficients for known CPU families.

2.7.1.1 Container-level implications

RAPL's granularity and domain separation make it suitable for correlating CPU energy usage with container activity, allowing for reasonably accurate attribution when combined with CPU usage metrics (e.g. cgroup CPU accounting or eBPF). In contrast, model-based estimations or ACPI-derived values are too coarse and lack temporal resolution, limiting their use to static or linear power distribution based on workload share, which is insufficient for fine-grained or bursty container workloads.

2.7.2 Memory

Memory power consumption can be measured using the DRAM domain exposed by Intel RAPL on supported server-grade processors. When available, this provides low-overhead, fine-grained energy telemetry integrated with other CPU domains. However, DRAM measurement accuracy depends heavily on processor architecture. It is generally reliable for Haswell-generation CPUs, but later architectures may exhibit a constant power offset or measurement inaccuracies due to off-DIMM voltage regulators and evolving memory subsystems.

If RAPL DRAM telemetry is unavailable or deemed unreliable, no equivalent in-band method exists. In such cases, estimation must rely on model-based approaches. Many models in the literature attempt to correlate memory power with usage, memory access frequency, or cache behavior, but they are not generalizable across systems. Most require prior calibration using known idle and peak memory power figures, which are rarely available in practice. Without these, estimation accuracy remains low. Manual insertion of idle and active power values from vendor datasheets can slightly improve results, but still yields only coarse-grained estimates.

2.7.2.1 Container-level implications

The RAPL DRAM domain, when accurate, allows correlation between energy consumption and workload-level memory metrics such as usage or memory bandwidth. This enables container-level attribution if per-container memory activity is available. Without RAPL, model-based estimates only support static or proportional energy attribution based on usage share, which is insufficient for capturing the energy impact of memory-intensive or bursty workloads.

2.7.3 GPU

Accurate GPU power measurement remains a challenge in containerized environments. The most accessible solution is NVIDIA's NVML interface (e.g. via nvidia-smi), which exposes power metrics through on-board sensors. While widely used, NVML suffers from sampling delays, averaging artifacts, and limited temporal resolution, especially during transient workloads. Nevertheless, it offers acceptable accuracy for steady-state measurements and is supported across many data center deployments.

Alternative tools, such as AccelWattch and FinGraV, provide finer temporal granularity and more precise modeling but are either architecture-specific or tightly coupled to particular hardware (e.g. AMD MI300X). Hardware-based solutions like PowerSensor3 achieve excellent accuracy at high sampling rates but are cost-prohibitive and impractical for large-scale deployment. No general-purpose, software-only solution currently matches the accuracy and portability of CPU-side tools like RAPL.

2.7.3.1 Container-level implications

GPU power attribution in Kubernetes is limited by the granularity and accuracy of current tools. While NVML can be queried from within containers or sidecars, it does not natively support multi-tenant attribution, and virtualization layers (e.g. vGPU, MIG) complicate per-container visibility. Accurate container-level GPU energy tracking remains an open problem, requiring either architectural integration (e.g. with MIG-aware scheduling) or improved temporal sampling. As such, GPU measurements are currently only viable for coarse-grained, workload-level profiling, not fine-grained container energy attribution.

2.7.4 Storage devices

Storage device energy consumption is typically estimated rather than measured. Unlike CPUs or GPUs, storage devices lack onboard power sensors, and BMC-based per-device readings are generally unavailable, especially when using backplanes, RAID controllers, or SATA interfaces. Consequently, power usage is inferred from device metrics and modeled behavior.

Telemetry is only available for specific device types. For NVMe drives, `nvme -cli` exposes detailed metrics such as supported power states, current power state, idle/active power ratings, and temperature. However, these are not available for SATA SSDs or HDDs. `smartctl` provides vendor-specific SMART data (e.g. temperature, power-on hours, wear) if available, but energy-related insights are limited. Standard Linux tools (`iostat`, `sar`, `/proc/diskstats`, etc.) expose generic performance counters such as IOPS, throughput, queue length, and utilization, which can support rough estimation.

Various model-based approaches estimate power using activity-based metrics (e.g. read/write rates or interface speed), often requiring idle and active power values from datasheets. These models are only accurate when tailored to specific hardware. No general-purpose estimator exists for unknown or heterogeneous storage types without prior calibration.

2.7.4.1 Container-level implications

Because disks are shared resources and per-container telemetry is unavailable, energy attribution must rely on proportional estimation using observable metrics like I/O volume or latency. This approach works for long-lived workloads but lacks the granularity to capture energy dynamics of bursty or short-lived container activity. Accurate container-level attribution remains infeasible for SATA SSDs and HDDs and is only marginally better for NVMe devices, assuming access to detailed device metrics.

2.7.5 Network devices

NIC power consumption cannot be measured directly via software. Although many cards support PCIe power states (e.g. D0–D3), these states only approximately correlate with actual power draw and are not sufficient for energy estimation. Furthermore, NICs lack onboard power sensors, and BMC-based per-device readings are generally unavailable. As such, NIC energy consumption must be estimated using model-based approaches.

Various research models estimate NIC power using idle and dynamic components. The most promising approach, proposed by Baneshi et al., linearly scales NIC power with bandwidth utilization, assuming idle and maximum power values are known. While earlier models correlate energy use with channel utilization or throughput, they often oversimplify or lack generalizability. Real-world measurements show minimal power variation between idle and active states (often <1W difference), with idle power dominating overall NIC energy use. Estimates can be improved slightly by incorporating known idle and peak wattage from datasheets, but generalization across different NICs remains unreliable due to architectural and vendor variability. In the absence of these values, the only remaining option is to guess these values based on NIC PHY medium.

Telemetry support is limited: tools like `ethtool` expose link speed and status but do not report power. No standard Linux tool provides direct NIC energy metrics, and throughput-based estimators must rely on indirect metrics like bytes transmitted per interval.

2.7.5.1 Container-level implications

Because NICs are shared across containers and lack per-container telemetry, only indirect attribution is possible. Energy consumption can be distributed proportionally based on container-level bandwidth usage (e.g. via cgroup network statistics), assuming idle and peak NIC power are known. However, the minimal dynamic variation in NIC power limits the usefulness of fine-grained attribution. In practice, NIC power is best modeled as a mostly static overhead, with marginal gains from utilization-based scaling.

2.7.6 Other Devices

Secondary components such as the motherboard, PSU, and fans contribute a non-trivial share to total server power consumption but are rarely modeled with precision. These devices typically lack direct power telemetry, and their energy use is either approximated or inferred indirectly.

PSU losses can be estimated from efficiency ratings if total input or output power is known. Fan power is difficult to measure and depends on physical factors like airflow and pressure; at best, it can be roughly estimated using RPM and vendor data. The motherboard and onboard controllers (e.g. voltage regulators, chipset) are usually modeled as part of residual power.

2.7.6.1 Best-practice approach

If system-level power data is available (e.g. via IPMI or Redfish), the difference between total server power and known component estimates can be treated as residual

power. This residual can be linearly distributed across containers based on the finer-grained power estimation of the CPU, assuming secondary device power scales with primary component power consumption.

2.7.6.2 Container-level implications

Because these components do not map directly to container usage, their energy must be attributed indirectly. Linear distribution based on known, container-attributed metrics (e.g. CPU time or workload duration) is a practical, though imprecise, fallback for ensuring full power accounting in containerized environments.

Chapter 3

Attributing Power Consumption to Containerized Workloads

3.1 Introduction and Context

While the previous chapter focused on system-level and component-level power measurement and estimation, this chapter shifts focus to an equally complex task: attributing measured server power consumption to the individual containers or workloads responsible for it.

Attributing energy consumption in this context is inherently difficult due to multi-tenant, multi-layered workloads across multiple CPU cores and devices, as well as temporal granularity mismatch issues. Consequently, direct one-to-one mapping of energy consumption to workloads is generally not possible.

Nonetheless, various techniques have emerged to approach this problem. The goal is to create an accurate and fair approximation of how much energy a given container or process is responsible for at any point in time. This chapter provides a conceptual foundation for these techniques. The subsequent [Chapter 4](#) will examine how selected tools implement these ideas in practice. While some implementation aspects will be referenced for illustration, this chapter focuses on general methodologies, not tool-specific behavior.

3.2 Power Attribution Methodology

3.2.1 The Central Idea Behind Power Attribution

At its core, the concept of power attribution is simple: a task should be held accountable for the energy consumed by the resources it actively uses. If a task occupies the CPU for a given period, it is attributed the energy consumed by the CPU during that time. By summing the energy usage of all tasks belonging to a container, one can estimate the total energy consumption of that container. Since energy is the integral of power over time, the average power consumption of a container can be calculated by dividing its attributed energy by the total duration of interest. Depending on the use case, either energy (in joules) or power (in watts) may provide more meaningful insight. Energy is often used to quantify cost or carbon footprint, while power helps identify peak loads and inefficiencies.

While this model appears intuitive, its implementation in real systems is far from trivial. One major complication stems from the intricacies of multitasking on modern systems, which is discussed in § 3.2.2. § 3.2.3 examines and compares different utilization tracking mechanisms in Linux and Kubernetes. As a result of the fine-grained temporal control of multitasking, another major challenge is temporal granularity. Power consumption is typically sampled at much coarser intervals than kernel resource usage statistics. These mismatched update rates and resolutions must be reconciled to build meaningful correlations. This issue is elaborated in § 3.2.4.

Consequently, power attribution becomes a complex algorithmic process, involving summation, weighting, and interpolation across multiple metrics. It must strike a balance between data availability and estimation accuracy. A perfectly accurate system is not feasible, especially in heterogeneous or production-grade environments. Limitations and accuracy trade-offs are further discussed in § 3.2.5. Finally, § 3.3 discusses the different philosophies of various attribution models to account for different key demographics.

Despite these difficulties, power attribution serves a critical role in understanding container behavior. If applied consistently across all containers and system resources, it can uncover the dynamic patterns of energy usage within a server. This insight forms a foundational building block for cluster-level energy optimization. Administrators or automated systems can use this data to analyze the effect of configuration changes, improve workload scheduling, or optimize performance-per-watt, whether during runtime or post-execution.

3.2.2 A Short Recap of Linux Multitasking and Execution Units

Linux is a multitasking operating system that enables multiple programs to run concurrently by managing how processor time is divided among tasks. This capability is central to container-based computing and directly impacts how workload activity is linked to energy consumption.

Multitasking in Linux operates on two levels: time-sharing on a single core and true parallel execution across multiple cores. On a single-core system, the kernel scheduler rapidly switches between tasks by allocating short time slices, creating the illusion of parallelism. On multi-core systems, tasks can run simultaneously on different cores, increasing throughput but also complicating the task of correlating resource usage with measured power consumption.

At the kernel level, the smallest unit of execution is a *task*. This term covers both user-space processes and threads, which the kernel treats uniformly in terms of scheduling and resource accounting. Each task is represented by a `task_struct`, which tracks its state, scheduling data, and resource usage.

A *process* is typically a task with its own address space. Threads, by contrast, share memory with their parent process but are scheduled independently. As a result, a multi-threaded program or container may generate several concurrent tasks, potentially running across multiple cores. These tasks are indistinguishable from processes in kernel metrics, which complicates aggregation unless care is taken to associate related threads correctly.

In containerized environments, tasks belonging to the same container are grouped

using Linux control groups (cgroups) and namespaces. These mechanisms allow the kernel to apply limits and collect resource usage statistics at the container level, making them central to energy attribution in Kubernetes-based systems.

3.2.3 Resource Utilization Tracking in Linux and Kubernetes

In modern Linux-based systems, particularly within Kubernetes environments, multiple methods exist to track resource utilization [30–33, 107, 108]. These methods vary significantly in terms of temporal granularity, scope, and origin. While they often expose overlapping information, their internal mechanisms differ, leading to trade-offs in precision, resolution, and suitability for certain use cases such as energy attribution.

3.2.3.1 CPU Utilization Tracking

- **/proc/stat:** A global, cumulative snapshot of CPU activity since boot. It records jiffies spent in user, system, idle, and iowait modes. Temporal resolution is high, but data is coarse and not process- or cgroup-specific.
- **/proc/<pid>:** Provides per-task CPU statistics including time spent in user and kernel mode. Offers fine-grained tracking on a per-process level but must be polled manually at high frequency to detect short-lived changes. Contains information about task container and namespace.
- **cgroups:** Tracks cumulative CPU usage in nanoseconds per cgroup. In Kubernetes, each container runs in its own cgroup, enabling container-level usage attribution. Granularity is high, and this is a foundational metric for tools like KEPLER and cAdvisor.
- **eBPF:** eBPF enables near-real-time tracking of per-task CPU cycles and execution, allowing correlation of resource usage to kernel events (e.g. context switches). It is especially valuable when precise attribution to short-lived tasks or containers is required.
- **Hybrid tools:** Many tools provide aggregated metrics and statistics based on the aforementioned methods. While user-friendly, these usually offer lower temporal precision, but may be useful in some instances. **cAdvisor:** collects and aggregates CPU usage per container by reading from cgroups. While widely used, its default update interval is coarse. Data is sampled and averaged, which limits its use in high-resolution analysis. **metrics-server (metrics.k8s.io):** exposes aggregated CPU usage via the Kubernetes API. It pulls metrics from Kubelet (which relies on cAdvisor) and is updated approximately every 15 seconds. Not suitable for precise or historical analysis.

3.2.3.2 Memory Utilization Tracking

- **/proc/meminfo:** Provides a system-wide view of memory usage but lacks per-task or per-container resolution.
- **/proc/<pid>/status:** Exposes memory-related counters for each process (e.g. RSS, PSS, virtual set size). Temporal granularity is fine but requires frequent polling.

- **cgroups (memory):** Records memory usage for groups of processes. `memory.usage_in_bytes` shows current memory usage per cgroup, allowing container-level tracking. High granularity and reliability, frequently used in both monitoring and enforcement.
- **cAdvisor and metrics-server:** As with CPU, memory stats are aggregated from cgroup data. These APIs offer lower resolution and no historical data.

3.2.3.3 Disk I/O Utilization Tracking

- **/proc/<pid>/io:** Tracks per-process I/O activity (bytes read/written, syscall counts). Useful for attributing I/O behavior, but coarse in how it correlates to actual disk access timing.
- **cgroups-v1 (blkio) / cgroups-v2 (io):** Reports aggregated I/O stats per cgroup (bytes, ops, per-device). Allows container-level attribution. Granularity depends on polling rate and support by the underlying I/O subsystem.
- **eBPF (tracepoints, kprobes):** Enables real-time tracing of block I/O syscalls, bio submission, and completion.

3.2.3.4 Network I/O Utilization Tracking

- **/proc/net/dev:** Shows network statistics per interface. Updated continuously, but lacks process/container granularity.
- **cgroups-v1 (net_cls, net_prio):** Used to mark packets with cgroup IDs, enabling traffic shaping and classification. Attribution is possible if paired with packet monitoring tools, but rarely used directly. While there is no direct equivalent in **cgroups-v2**, support was added in `iptables` to allow BPF filters that hook on cgroup v2 pathnames to control network traffic on a per-cgroup basis.
- **eBPF:** Allows tracing of network activity at various points in the stack (packet ingress, egress, socket calls). Offers very high granularity and can attribute traffic to specific containers.

3.2.3.5 eBPF-based Collection of Utilization Metrics

The extended Berkeley Packet Filter (eBPF) is a Linux kernel subsystem that allows the safe execution of user-defined programs within the kernel without modifying kernel source code or loading custom modules. Originally developed for low-level network packet filtering, eBPF has evolved into a general-purpose observability framework that can trace and monitor system events with high precision and minimal overhead. eBPF can be used to dynamically attach probes to kernel events such as context switches, system calls, I/O events, and tracepoints. In the context of system monitoring, this enables the collection of fine-grained utilization metrics, including CPU usage per process, memory allocations, and I/O activity, without modifying the monitored application. These probes run within the kernel and populate BPF maps, which can then be accessed by user-space tools to aggregate or export metrics.

Compared to traditional monitoring approaches such as reading from `/proc`, eBPF offers several key advantages. First, it supports high temporal resolution, enabling near real-time tracking of events. Second, it avoids the need for intrusive instrumentation or static tracepoints, making it suitable for black-box applications. Finally, its dynamic and event-driven nature reduces performance overhead by eliminating polling. As a consequence, eBPF has often been used for utilization monitoring: KEPLER uses eBPF to monitor CPU cycles and task scheduling events, enabling accurate attribution of resource usage to short-lived or highly dynamic workloads. It complements cgroup and perf-based metrics, allowing power attribution models to track containers that would otherwise be indistinguishable using standard polling-based methods.

As demonstrated by Cassagnes et al. [34], eBPF currently represents the best practice for non-intrusive, low-overhead, and high-resolution utilization monitoring on Linux systems. Its ability to gather container- or process-level metrics in production environments makes it uniquely well-suited for accurate correlation with system-wide power measurements.

3.2.3.6 Performance Counters and `perf`-based Monitoring

Modern processors expose hardware-level performance counters (PMCs) that can be used to obtain precise measurements of internal execution characteristics. These counters are accessible via tools such as `perf`, and include metrics such as retired instructions, CPU cycles, cache misses, branch mispredictions, and stalled cycles. Unlike traditional utilization metrics, which measure time spent in various CPU states, PMCs offer insight into how effectively the processor is executing instructions.

A particularly relevant metric is *instructions per cycle* (IPC), which quantifies how much useful work is being done per clock cycle. An IPC close to the CPU's architectural maximum indicates efficient execution, while lower values often signal bottlenecks such as memory stalls. As shown by Gregg[35], a low IPC may reveal that the processor is heavily stalled, even when CPU utilization appears high.

These metrics provide a powerful alternative for workload analysis and energy estimation. For instance, instruction counts can be used to normalize energy usage per task, enabling attribution models that go beyond time-based utilization.

However, access to PMCs is not always guaranteed. In virtualized environments and some container runtimes, performance counters may be inaccessible or imprecise due to hypervisor restrictions. Moreover, interpreting raw PMC values requires architectural knowledge and hardware-specific calibration.

3.2.3.7 Comparative Summary

3.2.4 Temporal Granularity and Measurement Resolution

To correlate CPU usage with power consumption, time must be considered at an appropriate granularity. The Linux kernel tracks CPU usage at the level of scheduler ticks, which are driven by a system-wide timer interrupt configured via `CONFIG_HZ`. Typical values range from 250 to 1000 Hz, meaning time slices of 4 to 1 milliseconds, respectively. These ticks, or *jiffies*, represent the smallest scheduling time unit and are used to increment counters such as `utime` and `stime` for each task.

Source	Granularity	Scope	Notes
/proc/stat	Medium	Global	Jiffy-based, coarse
/proc/<pid>/stat	High	Per-process	Fine-grained, must poll manually
cgroups	High	Per-cgroup	Foundation for container metrics
cAdvisor	Medium-Low	Per-container	Aggregated from cgroups, limited rate
eBPF	Very High	Per-task, system-wide	Real-time, customizable, low overhead
perf/PMCs	Very High	Per-task, core-level	Tracks cycles, instructions, stalls

TABLE 3.1: Comparison of resource usage tracking mechanisms

More modern interfaces (such as cgroup v2’s `cpu.stat`) provide higher-resolution timestamps, often in nanoseconds, depending on the kernel version and configuration.

In contrast, power measurement tools generally operate at coarser time resolutions. Intel RAPL, for example, may expose updates every few milliseconds to hundreds of milliseconds, while BMC- or IPMI-based readings typically update once per second or slower. As a result, power attribution techniques must reconcile the high-frequency task activity data with lower-frequency power measurements, often through aggregation or interpolation over common time intervals.

A clear understanding of these execution and timing units is essential for building reliable power attribution models. These concepts underpin all subsequent steps, including metric fusion, resource accounting, and workload-level aggregation.

3.2.5 Challenges

System monitoring and the attribution of power metrics based on system (and component) utilization metrics introduce several challenges that need to be addressed by a power attribution methodology. Some of these represent natural trade-offs that an architect needs to be aware of, while others pose issues that simply cannot be circumvented without major drawbacks that cannot be solved with a suitable architecture.

3.2.5.1 Temporal Granularity and Synchronization

A central challenge in power attribution is the mismatch in temporal granularity between system and power metrics. High-resolution sources, such as eBPF-based monitoring, can distinguish variations within individual CPU time slices. In contrast, coarse-grained power metrics (such as IPMI) often update only once per second, rendering them unable to reflect fine-grained container activity. Metrics like RAPL fall in between, typically sampled at up to 1000 Hz but practically stable at around 50 Hz. Model-based estimators may match the granularity of their input metrics or, in simpler cases, use time-based assumptions with theoretically unlimited granularity.

These disparities make straightforward correlation difficult. While coarse metrics like IPMI provide broad system power data (including components invisible to fine-grained tools), they should not be interpolated to finer time scales, as doing so introduces artificial detail and potential misattribution. Instead, they are best treated as low-frequency anchors to validate or constrain high-resolution estimates. For example, summed RAPL readings can be compared to IPMI over aligned intervals, though their differing measurement scopes add complexity.

Another complication is temporal skew. Even metrics with similar frequencies are rarely sampled simultaneously, and some introduce unknown or variable delays. This misalignment creates ambiguity between observed utilization and corresponding power draw, particularly for short-lived or rapidly changing workloads. Naïve smoothing may reduce noise but also obscures meaningful transient behavior.

Effective attribution therefore requires more than just aligning timestamps. It demands awareness of each metric’s origin, behavior, and limitations, and careful coordination to avoid erroneous correlations and preserve meaningful detail.

3.2.5.2 Challenges in CPU Metric Interpretation

CPU utilization is one of the most accessible and commonly used metrics to quantify processing activity on modern systems. It is widely reported by system monitoring tools such as `top`, `htop`, and cloud APIs, and is frequently used in both performance diagnostics and energy attribution models. However, despite its ubiquity, the interpretation of CPU utilization is far from straightforward, and in many contexts, it is misleading.

At its core, CPU utilization is a time-based metric that represents the proportion of time a CPU spends executing non-idle tasks. In Linux, this value is computed from counters in `/proc/stat` and reported in units of “jiffies”. It distinguishes between various states (user, system, idle, I/O wait, interrupts) but ultimately expresses how long the CPU was busy, not how much useful work it performed[109].

A fundamental limitation is that CPU utilization conflates time with effort. Not all CPU time is equally productive: some cycles may execute complex, compute-intensive instructions, while others may stall waiting for memory I/O. Modern CPUs are frequently memory-bound due to the growing performance gap between processor speed and DRAM latency. As a result, a high CPU utilization value may indicate that the processor was merely stalled, not that it was the performance bottleneck[35].

These nuances have direct consequences for energy attribution. When energy models allocate power proportionally to CPU utilization, they assume a linear relationship between time and energy. However, power consumption depends heavily on the instruction mix, CPU frequency scaling, Turbo Boost, and simultaneous multi-threading. In such environments, identical utilization values across different processes or intervals may reflect vastly different energy profiles.

A more accurate alternative is to use hardware performance counters (PMCs), which track low-level metrics such as instructions retired, cache misses, and stalled cycles. For example, the “instructions per cycle” (IPC) value provides insight into how effectively the CPU executes work during its active time. An IPC significantly below the processor’s theoretical maximum often indicates a memory-bound workload, while

high IPC values suggest instruction-bound behavior. Tools like `perf` or `tiptop` can expose such metrics, though their use may be restricted in virtualized environments.

In summary, CPU utilization should be treated with caution, especially in the context of energy-aware scheduling and workload attribution. As Cockcroft already argued in 2006, utilization as a metric is fundamentally broken[110]. Practitioners are advised to:

- Avoid assuming a linear relationship between CPU utilization and power consumption.
- Consider supplementing utilization metrics with performance counters (e.g. IPC, cycles, instructions) when available.
- Be mindful of the measurement interval and sampling effects in tools like *Scaphandre*.
- In energy models, explicitly account for idle power, and avoid assigning it solely to active processes.
- Prefer instruction-based metrics for finer granularity and better correlation with energy use.

3.2.5.3 Availability of Metrics

The availability of system and power metrics varies widely between platforms. While some systems offer high-resolution data, others may only expose coarse values or lack direct power data entirely. An effective attribution system should dynamically adapt to the metrics available, incorporating new sources (such as wall power meters) as they are added.

Ideally, such a system would also communicate the trade-offs involved, indicating how metric availability affects accuracy and granularity. This transparency ensures that attribution results are interpreted with appropriate context and helps guide improvements in monitoring fidelity.

Attribution in Multi-Tenant and Shared Environments

In multi-tenant systems, not all resources can be cleanly partitioned or measured with sufficient precision for container-level attribution. Some components are inherently shared, and their energy use cannot be isolated to individual workloads. Additionally, system-wide energy consumers like power supplies, cooling fans, and idle background services contribute to total power draw but are not tied to any specific container. Attribution models must account for these shared and unaccountable energy domains. Addressing these concerns requires careful modeling and philosophical choices about how to treat unassigned energy, which are further discussed in § 3.3.

Measurement Overhead

All monitoring systems inherently introduce some degree of overhead. While modern tools such as eBPF are designed to minimize this impact, they still consume CPU

cycles and memory bandwidth. Lightweight tools can reduce overhead without sacrificing data quality, but complete elimination is not possible.

Notably, the cost of monitoring increases with temporal resolution. Fine-grained metrics require higher sampling rates, more frequent data transfers, and additional processing effort. Since container-level power metrics typically do not require sub-second resolution, it is essential that high-resolution analysis and correlation occur as early as possible in the data pipeline. By aggregating and attributing power consumption close to the source, downstream systems can operate on compact, coarse-grained results, reducing both computational and storage overhead while preserving attribution accuracy.

Support for Evolving Models

As hardware platforms and research in power estimation continue to evolve, new measurement interfaces and modeling approaches are regularly introduced. These may offer improved accuracy, reduced overhead, or better coverage of previously unobservable components. To remain relevant and effective, container-level power attribution systems must be designed with adaptability in mind. A modular architecture enables the integration of new data sources or estimation models without reengineering the entire system. This flexibility ensures long-term maintainability and allows the system to benefit from ongoing advancements in energy modeling and monitoring infrastructure.

3.3 Attribution Philosophies

Attributing server power consumption to individual containers requires decisions that go beyond data collection. Some components are inherently shared, some workloads contribute system-level overhead, and some energy is consumed by idle hardware. The way these factors are treated reflects the underlying attribution philosophy. This section outlines three main approaches, each suitable for different goals and users.

3.3.1 Container-Centric Attribution

This model attributes energy solely based on the direct activity of containers, ignoring system services and shared infrastructure. Remaining resources are pooled and can be declared as system resources. This means that a container is not accountable for its own orchestration or energy wasted through system idling.

- **Advantages:** Isolates workload impact; consistent across system loads.
- **Limitations:** Understates real-world cost; excludes orchestration and idling overhead.
- **Suitable for:** Developers optimizing containerized applications.

Notably, container-centric attribution places a strong emphasis on individual containers and their respective energy consumption, striving to maintain relative consistency irrespective of overall cluster activity. While such granular insights can be valuable to developers, container-centric attribution typically does not represent the

primary practical use case of an energy monitoring system for Kubernetes containers. This is largely due to the container isolation principle, which usually restricts detailed visibility into broader system dynamics. Additionally, container-level optimization is often more effectively achieved through simpler CPU and memory metrics readily accessible via the container's own `/proc` filesystem. Hence, although technically feasible, container-centric energy attribution often remains primarily a theoretical or research-oriented concept rather than a widely implemented practical approach.

3.3.2 Shared-Cost Attribution

Here, all power consumption is distributed across active containers, either equally or proportionally to usage. As a consequence, a container is accountable for its own orchestration, its share of OS resources, and even energy wasted through system idling.

- **Advantages:** More accurately reflects total system cost.
- **Limitations:** Attribution fluctuates with container count; depends on arbitrary distribution logic.
- **Suitable for:** Cluster operators optimizing cluster orchestration.

3.3.3 Explicit Residual Modeling

Beyond the container-centric and shared-cost attribution models lies a more nuanced approach that explicitly incorporates the efficiency characteristics of server hardware. In this model, total power consumption is divided not only among containers and system services but also includes separate terms for idle power and high-utilization overhead. Idle power represents the baseline energy required to keep the system operational, even when no meaningful work is being performed. However, this value is difficult to isolate, as it often overlaps with low-level system activity such as kernel threads, background daemons, or monitoring agents.

At the other end of the spectrum, when utilization approaches system limits, energy efficiency typically degrades due to resource contention, frequent context switching, and thermal throttling[111]. These effects increase energy consumption without proportional performance gains. To account for these dynamics, this model introduces two residual domains (*idle waste* and *efficiency overhead*), which reflect conditions not attributable to any specific container. While this model is more complex, it enables more accurate assessment of workload behavior, infrastructure utilization, and waste, making it particularly valuable for research, performance engineering, and sustainability analysis.

Challenges in Measuring Residuals. Despite its advantages, implementing this model is non-trivial due to the difficulty of distinguishing idle consumption and overhead effects from general system resource usage:

Idle power estimation

- **Shared background activity:** Even in idle states, kernel tasks and system services introduce minimal but nonzero load, making it hard to define a “pure” idle baseline.
- **C-state transitions:** CPUs may briefly exit low-power states due to timers or interrupts, causing fluctuations even during apparent idleness.
- **Isolation difficulty:** In production or multi-tenant environments, isolating a server to a truly idle state is often impractical.

High-utilization overhead

- **Lack of a clear baseline:** There is no standard definition of “ideal” energy usage at full utilization, complicating quantification of overhead.
- **Architecture-specific behavior:** Overheads from cache contention, memory stalls, or I/O bottlenecks depend heavily on the workload and hardware architecture.

Due to their complexity and variability, high-utilization overhead effects are excluded from the scope of this thesis. This is a minor limitation, as assigning this energy to general *system* consumption remains a valid and conservative approach.

Practical Approach to Idle Estimation. In practice, idle consumption can be estimated pragmatically by recording power usage while no user workload is running. While this conflates pure idle consumption with background system activity, the trade-off is acceptable given its simplicity and reproducibility.

The resulting hybrid model separates power into three categories:

$$P_{\text{total}} = \sum P_{\text{container}} + P_{\text{system}} + P_{\text{idle}} \quad (3.1)$$

Residual power not attributed to container workloads is explicitly labeled as *system* or *idle* consumption. (In some literature, the term *static* is used in place of *idle*.)

- **Advantages:** Transparent; enables both container-level and infrastructure-level analysis.
- **Limitations:** Requires high-quality telemetry; boundaries between idle and system power are inherently fuzzy.
- **Best suited for:** Research, cluster optimization, and sustainability reporting.

In real-world scenarios, this model provides cluster operators with the foundation for quantitative infrastructure efficiency analysis. At the same time, developers benefit from a consistent, workload-centric power metric that reflects the true resource cost of their container, independent of the activity of co-located workloads.

3.3.4 Distinction Between CPU Idling and Process Idling

A CPU is considered **idle** when it has no runnable tasks. In this case, the Linux scheduler runs a special task called the *idle task* (PID 0), and the processor may enter a low-power idle state to save energy. The time spent in this state is what is reported

as CPU idle time. The *idle task* is not shown in `/proc` and similar interfaces because it is only internally used by the scheduler, and not a regular process.

A process, on the other hand, does not truly idle in kernel terms. When a process is not using the CPU (because it is waiting for I/O, a timer, or another event), it is in a *sleeping* or *blocked* state. Although it may appear inactive, it is still managed by the scheduler and may resume execution when its blocking condition is resolved.

The key distinction is that **only CPUs idle** in the kernel's formal sense. A CPU idles when it has no work to do, while a process never truly idles: it either runs, waits, or is terminated.

Chapter 4

Approaches and Tools for Container Energy Measurement

4.1 Introduction

Accurately measuring and attributing energy consumption in containerized environments has become a central challenge in sustainable cloud computing. As container orchestration platforms like Kubernetes grow in adoption, the need for energy observability at finer granularities (down to the container or even process level) becomes increasingly critical. This requirement stems from a range of applications, including cost optimization, carbon accounting, energy-aware scheduling, and performance tuning.

A number of tools and frameworks have emerged in recent years to address this problem. Some focus on the system or server level, exposing power metrics via standardized interfaces or external instrumentation. Others adopt telemetry-based estimation approaches that infer energy usage from resource utilization statistics. More recently, several tools have begun to target container-level energy attribution specifically, often by integrating with Kubernetes and leveraging technologies such as eBPF, RAPL, and cgroups.

This chapter surveys the landscape of existing tools, organized into three categories: system-level monitoring solutions, telemetry-based estimation frameworks, and container-focused energy attribution tools. Particular attention is given to tools that support Kubernetes environments, as these are directly relevant to the goals of this thesis. Each tool is analyzed based on its architecture, metric sources, modeling approach, and practical limitations. Later sections discuss the emerging tool KubeWatt and present a comparative synthesis of strengths and weaknesses across the reviewed solutions.

4.2 Non-container-focused Energy Monitoring Tools

4.2.1 Server-Level Energy Monitoring

While not directly translatable to container-level energy monitoring, server-level energy consumption remains an important aspect. Scientific works and tools in this domain generally do not provide the temporal resolution required for container-level energy monitoring.

4.2.1.1 Kavanagh and Djemame: Energy Modeling via IPMI and RAPL Calibration

Overview and Architecture Kavanagh and Djemame[12] present their findings on combining IPMI and RAPL (interface unspecified) data to estimate server energy consumption, achieving improved accuracy through calibration with an external server-level watt meter. For calibration, they induce artificial CPU workloads and rely on CPU utilization metrics with 1-minute averaging windows, necessitating extended calibration intervals to obtain stable readings. While the resulting model is tailored to their specific hardware and not generally portable, their work provides valuable insights into the complementary use of IPMI and RAPL. The authors recognize that the respective limitations of these tools (RAPL’s partial scope and IPMI’s low resolution) can be mitigated when used in combination.

Attribution Method and Scope Although the model operates at the physical host level, it supports attribution to VMs or applications using CPU-utilization-based proportional allocation. Several allocation rules are proposed, including utilization ratio, adjusted idle sharing, and equal distribution. However, no container-level attribution is attempted, and runtime flexibility is limited due to the static nature of the calibration.

Validation and Limitations With their watt-meter-calibrated model using segmented linear regression, the authors report an average error of just -0.17%. More relevant to practical application, they also construct a model based solely on IPMI and RAPL (calibrated via watt meter data), which achieves a reduced error of -5.58%, compared to -15.75% without calibration. Limitations of their approach include the need for controlled, synthetic workloads, coarse-grained sensor input, and the assumption of relatively stable system conditions during calibration.

Key Contributions

- **Hybrid use of IPMI and RAPL is analyzed**, showing that these tools compensate for each other’s limitations. RAPL underestimates total system power, while IPMI captures more components but at lower resolution.
- IPMI accuracy is significantly improved through external watt meter calibration.
- The authors provide practical calibration guidelines:
 - Use long, static workload plateaus to align with averaging windows and reduce synchronization complexity.
 - Discard initial and final measurement intervals to avoid transient noise and averaging artifacts.
 - Ensure calibration workloads exceed the IPMI averaging window to capture valid steady-state values.

Relevance to Proposed Architecture This work informs the proposed architecture by demonstrating how combining RAPL and IPMI can yield more accurate system-level power estimation. The use of plateau-based calibration and composite data

models is especially applicable. However, the lack of container-level granularity, reliance on offline calibration, and limited attribution scope underscore the need for more dynamic, fine-grained, and container-aware approaches in Kubernetes-based environments.

4.2.1.2 CodeCarbon

CodeCarbon[112] is a Python package designed to estimate the carbon emissions of a program’s execution. While its implementation is general-purpose, it is primarily aimed at machine learning workloads.

Overview and Architecture CodeCarbon estimates a workload’s energy consumption by relying on RAPL *package-domain* CPU metrics via the `powercap` RAPL file system interface. A fix for the RAPL MSR overflow issue was implemented[113]. In the absence of RAPL support, it falls back to a simplified model based on the CPU’s Thermal Design Power (TDP), obtained from an internal database, and combines it with CPU load metrics from `psutil`. For memory, a static power value is assumed based on the number and capacity of installed DIMMs. GPU power consumption is estimated via NVIDIA’s NVML interface. The default measurement interval is 15 seconds, with the authors citing lightweight design as the primary motivation.

The component-level estimations are then aggregated and multiplied by a region-specific net carbon intensity (based on the local electricity grid’s energy mix) to estimate the program’s total CO₂ emissions. CodeCarbon is typically executed as a wrapper around code blocks, scripts, or Python processes.

Limitations There is no direct attribution of CPU activity to individual power metrics: CodeCarbon estimates energy use indirectly, based on the number of active cores and average CPU utilization, while making many assumptions that could be prevented. Combined with the relatively long measurement intervals, this results in background system processes also being attributed to the measured Python program. Consequently, CodeCarbon does not contribute directly to the goals of this thesis, which seeks fine-grained, container-level attribution.

However, the tool highlights several interesting secondary considerations. The integration of regional CO₂ intensity data is a valuable extension to conventional energy measurement and is well implemented. Additionally, the Python-based design offers high accessibility and ease of use, which may serve as inspiration for future developer-facing tools.

4.2.1.3 AI Power Meter

AI Power Meter[114] is a lightweight Python-based tool designed to monitor the energy consumption of machine learning workloads. It gathers power consumption data for the CPU and RAM via Intel RAPL using the `powercap` interface, and for the GPU via NVIDIA’s NVML library. While the authors acknowledge that other system components (e.g. storage, network) also contribute to energy usage, these are not currently included and are considered an accepted limitation of the tool.

Unlike more advanced attribution tools, AI Power Meter does not distinguish between individual processes or workloads. Instead, it provides coarse-grained, system-level energy consumption measurements over time. In this respect, its scope is similar to *CodeCarbon*, focusing on ease of use and integration into ML pipelines rather than precise, per-process energy attribution. As such, while not directly applicable to container-level measurement or power attribution, AI Power Meter demonstrates the growing interest in accessible energy monitoring tools within the machine learning community.

4.2.2 Telemetry-Based Estimation Frameworks

4.2.2.1 PowerAPI Ecosystem[115] (PowerAPI, HWPC, SmartWatts)

PowerAPI[116] is an open-source middleware toolkit for assembling software-defined power meters that estimate real-time power consumption of software workloads. Developed as a generalized and modular framework, PowerAPI evolved alongside specific implementations such as *SmartWatts*, detailed in § 4.3.3. It allows power attribution at multiple granularity levels, including processes, threads, containers, and virtual machines. A distinctive strength of PowerAPI is the continuous self-calibration of its power models, enabling accurate real-time energy estimation under varying workloads and execution conditions. This makes PowerAPI particularly suited to heterogeneous computing infrastructures.

Overview and Architecture PowerAPI uses an actor-based model for modularity, enabling easy customization of its internal components with minimal coupling. It supports raw metric acquisition from diverse sensors (e.g. physical meters, processor interfaces, hardware counters, OS counters) and delivers power consumption data through various output channels (including files, network sockets, web interfaces, and visualization tools). As middleware, PowerAPI facilitates assembling power meters "*à la carte*" to accommodate specific user requirements and deployment scenarios.

Core Components

- **powerapi-core:** Middleware orchestrating real-time/post-mortem interactions between sensors and formulas. It defines the essential interfaces for sensor data ingestion and output channels (e.g. MongoDB, InfluxDB, CSV, socket, Prometheus), and includes built-in capabilities for data preprocessing, post-processing, and reporting.
- **hwpc-sensor:** A telemetry probe designed to gather low-level hardware performance counters (HWPCs), including instructions, cycles, and RAPL energy metrics. This sensor leverages *perf* and *cgroups-v2*, critical for fine-grained telemetry in containerized environments. It also provides detailed CPU performance state metrics via MSR events (TSC, APERF, MPERF).
- **SmartWatts-formula[54]:** A power model implementation (in Python) using HWPC data to estimate power consumption dynamically. It employs online linear regression provided by the Python *scikit-learn*[117] library, enabling accurate runtime learning of workload-specific power signatures. SmartWatts is further detailed in § 4.3.3.

- **SelfWatts-controller:** Dynamically selects hardware performance counters for software-defined power models, facilitating automatic configuration and unsupervised deployment in heterogeneous infrastructures. Currently, its development has stalled for several years, limiting its practical applicability.
- **pyRAPL:** A convenient Python wrapper around RAPL for CPU, DRAM, and iGPU energy metrics collection, providing easy access to hardware-based power data.

Relevance and Integration The modular and extensible architecture of PowerAPI positions it as a highly suitable foundation for further research and development of specialized power attribution tools. Researchers can readily extend or adapt its components to address evolving or niche requirements. However, its current implementation does not incorporate certain critical metrics, such as IPMI-based telemetry, which could limit its completeness in some practical deployment scenarios. Nonetheless, PowerAPI represents a significant advancement toward the creation of generalized, plug-and-play power models that operate without extensive manual calibration. This emphasis on practical deployability and general applicability highlights a key strength of the project and sets a clear direction for future research and development efforts in the domain of software-defined energy monitoring.

4.2.2.2 Green Metrics Tool

The *Green Metrics Tool* (GMT)[118] is an open-source framework designed to measure the energy consumption of containerized applications across various phases of the software lifecycle, including installation, boot, runtime, idle, and removal. It uses small, modular metric collectors to gather host-level energy and system data (e.g. CPU and DRAM energy via RAPL, IPMI power readings), and is orchestrated through declarative usage scenarios.

While GMT provides reproducible, lifecycle-aware measurements in controlled environments, it does *not* perform container-level or process-level energy attribution. The developers explicitly avoid splitting energy consumption across containers, citing the lack of reliable attribution models.

4.3 Container-Focused Energy Attribution Tools

While system-level monitoring and telemetry-based estimation provide valuable insights into overall server energy consumption, they fall short when it comes to attributing energy use to individual containers. In multi-tenant or microservice-based environments, such granularity is essential for accurate accountability, optimization, and scheduling decisions.

This section focuses on tools specifically designed to address this challenge by providing energy attribution at the level of containers or processes within a containerized environment. These tools typically integrate with container runtimes and Kubernetes, leveraging sources such as hardware counters, control groups, and performance monitoring frameworks to estimate or infer energy consumption.

The following subsections analyze three prominent tools (Kepler, Scaphandre, and SmartWatts), each with a distinct architectural approach. A fourth tool, KubeWatt, is discussed separately as a derivative implementation developed in response to identified limitations in Kepler.

4.3.1 Kepler

4.3.1.1 Overview and Goals

Kepler (*Kubernetes-based Efficient Power Level Exporter*)^[49] is a modular, Kubernetes-native framework for monitoring, modeling, and estimating energy consumption in containerized environments. As the most prominent tool for container-level power estimation in Kubernetes, Kepler enables detailed observability of energy usage at the level of individual processes, containers, pods, and nodes^[119].

Kepler integrates seamlessly with Kubernetes and Prometheus-based observability stacks. It supports both real-time energy metrics (e.g. RAPL, ACPI, NVML) and model-based estimation through trained regression models, making it applicable across a wide range of deployment environments, from bare-metal servers to virtual machines. Developed as an open-source CNCF project, Kepler's architecture is designed to be extensible, allowing researchers and practitioners to contribute new power models and adapt it to diverse system architectures.

It should be noted that shortly before the completion of this thesis, version 0.10.0 of Kepler was released. This version constitutes a major architectural rewrite of the project, intended to address structural limitations of earlier versions. However, the analysis in this chapter focuses on Kepler versions 0.9.x and earlier, which remain the most widely deployed at the time of writing. § 4.3.1.8 briefly summarizes the key changes introduced in the new release.

4.3.1.2 Architecture and Metric Sources

Kepler's architecture consists of several interconnected components, with the core functionality centered around a privileged monitoring agent that runs on every node. While the framework supports model-based estimation for environments without hardware telemetry, this thesis focuses on the direct collection of real-time power and utilization metrics available in bare-metal deployments.

Deployment Models Kepler supports multiple deployment scenarios depending on the availability of energy sensors on the host system. In bare-metal environments, Kepler can directly collect power metrics using RAPL, ACPI, or Redfish/IPMI interfaces. This is the most accurate and relevant mode for the purpose of this thesis. In contrast, on virtual machines (VMs), where access to hardware counters or power interfaces is restricted, Kepler relies on trained regression models to estimate node-level energy consumption. A third, currently unimplemented deployment model proposes a passthrough mechanism where a host-level Kepler instance would expose power metrics to a nested Kepler instance inside the VM. These deployment models are visualized in figure 4.1.

Kepler Agent and Exporter The core monitoring functionality is handled by the Kepler Agent, which is deployed as a privileged DaemonSet pod on each Kubernetes node. It collects energy and resource utilization metrics using a combination

FIGURE 4.1: Kepler deployment models: direct power measurement on bare-metal, estimation on VMs, and the proposed passthrough model (currently not implemented)[120]

of eBPF instrumentation and hardware performance counters exposed via `perf_event_open`. A kprobe attached to the `finish_task_switch` kernel function enables accurate tracking of per-process context-switch activity. Container and pod attribution is performed after parsing the cgroup path from `/proc/<pid>/cgroup` and querying the Kubelet API for container metadata. The generated metrics are exported via a Prometheus-compatible endpoint for downstream processing and visualization. A generalized information flow is shown in figure 4.2.

FIGURE 4.2: Simplified architecture of the Kepler monitoring agent and exporter components[120]

Resource Utilization via eBPF-based Hardware/Software Counters To measure low-level CPU activity, Kepler uses the Linux syscall `perf_event_open` to configure hardware performance counters on each core. The following events are tracked:

- `PERF_COUNT_HW_CPU_CYCLES`: Total CPU cycles (affected by DVFS)
- `PERF_COUNT_HW_REF_CPU_CYCLES`: Frequency-independent cycles
- `PERF_COUNT_HW_INSTRUCTIONS`: Retired instructions

- `PERF_COUNT_HW_CACHE_MISSES`: Last-level cache misses

These counters are accessed via BPF perf event arrays. On each context switch, current counter values are sampled, and deltas are computed against previously stored values. These deltas represent the CPU activity of the process leaving the CPU and are stored in BPF maps for later aggregation.

In addition to hardware counters, Kepler collects several software-level metrics that are not natively exposed by the Linux kernel. These include CPU time, page cache activity, and interrupt handling statistics. Because these metrics are unavailable through standard interfaces, Kepler uses custom eBPF programs to infer them from kernel behavior.

Since version 0.7, Kepler has migrated to `libbpf` and uses a BTF-enabled kprobe to instrument the `sched_switch` function. This allows Kepler to safely extract process IDs and timing data without relying on fragile symbol offsets. On each context switch, Kepler records timestamps and uses them to increment the `CPUTime` counter, providing fine-grained accounting of CPU residency per process.

Other software counters include:

- `PageCacheHit`: Tracks read and write access to the page cache using eBPF programs attached to `mark_page_accessed` and `writeback_dirty_folio`.
- `IRQNetTX`, `IRQNetRX`, `IRQBlock`: Count the number of softirq events attributed to a process, using the `softirq_entry` tracepoint.

Each of these metrics is manually accumulated in eBPF maps keyed by process ID and periodically read by the user-space collector. This enhances energy attribution, especially in scenarios where hardware counters are insufficient or unavailable.

Node Component-level Energy Consumption via RAPL Kepler supports component-level power estimation by reading RAPL energy counters, focusing on the `core`, `uncore`, `package`, and `dram` domains. The energy values are read via the `PowerCap` framework using the `/sys/class/powercap` interface. The sysfs path tree is parsed dynamically to detect available domains and sockets, ensuring compatibility across architectures and CPU generations. Energy values are read directly from files such as `energy_uj` and divided by 1000 to yield millijoule-level readings. A wraparound detection mechanism ensures robustness even when energy counters overflow.

The core logic is implemented in `UpdateProcessEnergy()`, which is invoked periodically by the main metrics collection loop (and also calls the process attribution logic immediately after the metrics update). However, despite RAPL's native ability to provide energy readings at approximately millisecond-level resolution, Kepler limits energy sampling to a coarse default interval of three seconds (defined in `config.SamplePeriodSec`). This choice reflects a trade-off between performance overhead and metric granularity but may limit accuracy for short-lived or bursty workloads.

Importantly, Kepler does not rely on eBPF or perf events to retrieve energy values; energy is obtained entirely through file-based reads from sysfs or, on some platforms, via MSR or hwmon fallbacks. The collected energy values are later exposed

to Prometheus and used in model training and runtime inference. The measurement cadence, attribution methodology, and available domains are validated using an internal tool that checks domain availability and collects average power readings across repeated samples.

Platform-Level Energy Consumption Kepler supports platform-level energy monitoring through external power interfaces exposed by the underlying server hardware. These measurements represent the total energy consumed by the entire node, as opposed to specific hardware components or processes. The implementation is modular, with each power source encapsulated in a corresponding `source` module. Currently supported backends include ACPI (via the `/sys/class/hwmon` interface), Redfish (via the Redfish REST API), and a stub for IBM's HMC interface on `s390x` systems.

Among these, Redfish provides the most detailed and reliable node-level power data. It queries the server's BMC for the `PowerConsumedWatts` value using a REST endpoint. This value is then converted into energy (in millijoules) by multiplying with the time elapsed since the previous query. Kepler spawns a background goroutine that polls this value at regular intervals (user-configurable via the `REDFISH_PROBE_INTERVAL_IN_SECONDS` parameter in the Kepler configuration). This design allows Redfish to provide cumulative energy measurements with known sampling resolution.

ACPI-based sources offer an alternative when Redfish is unavailable. These rely on instantaneous power averages and do not necessarily represent total node power. The HMC source, by contrast, is currently a non-functional placeholder used only on unsupported platforms. Overall, platform-level metrics are treated as node-wide aggregate energy values without internal attribution, but they offer valuable ground truth for cross-validating other metrics or monitoring infrastructure-level power trends.

Metadata Inputs for Container, System, and VM Attribution To organize energy and resource metrics by container, Kepler collects metadata that maps processes to Kubernetes pods, containers, and namespaces. Kepler supports both cgroups v1 and v2 and dynamically traverses `/sys/fs/cgroup` to map `PID` or `cgroupID` values to container IDs, extracting the last 64 characters of valid cgroup paths.

If the container ID is not cached, Kepler queries Kubernetes for pod metadata using either the Kubelet's local `/pods` API or, if enabled, the Kubernetes API server via a dedicated watcher. Both approaches extract metadata from `ContainerStatuses` fields in pod objects and populate a shared cache. This includes support for init and ephemeral containers. Container ID prefixes are stripped using regex to standardize the format.

Processes not associated with a container are labeled using fallback logic. If the process belongs to the root cgroup (`cgroupID = 1`) and cgroup-based resolution is enabled, it is labeled `container="kernel_processes", namespace="kernel"`. All other unmapped processes are labeled `container="system_processes", namespace="system"`. This includes host services such as `kubelet` and `containerd`. The Linux idle thread (PID 0), which does not appear in `/proc` and cannot be queried like regular processes, is not explicitly handled by Kepler; however, since

it belongs to the root cgroup implicitly, it is effectively included under the `kernel_processes` label.

In addition to container and system process tracking, Kepler supports experimental attribution for virtual machines running under QEMU/KVM on the host. When executed on the hypervisor, Kepler scans `/proc/<pid>/cgroup` for scope names matching the systemd pattern `machine-qemu-*.scope` to identify VM processes. If a match is found, the VM ID is extracted and used to create a `VMStats` structure, allowing the VM to be tracked similarly to a container. Optionally, a metadata lookup via the libvirt API can be used to resolve human-readable VM identifiers. This enables Kepler to expose VM-level resource and energy metrics on systems that mix containers and virtual machines. However, this mechanism only applies to Kepler instances running on the VM host and does not provide visibility into containers running inside the VM.

This metadata layer allows Kepler to cleanly separate containerized workloads, system processes, kernel activity, and virtual machines, ensuring complete coverage of energy attribution in subsequent stages.

GPU Power and Resource Utilization via NVML Kepler collects per-process GPU utilization statistics using the NVIDIA Management Library, accessed through internal Go bindings. Specifically, Kepler queries both compute engine usage and memory utilization for each process interacting with an NVIDIA GPU. This data is retrieved via the `ProcessResourceUtilizationPerDevice()` method, which internally calls NVML functions like `nvmlDevice.GetProcessUtilization` to return process statistics, including Streaming Multiprocessor utilization (`SmUtil`), memory utilization (`MemUtil`), and optional encoding/decoding activity. Additionally, Kepler collects GPU energy consumption using NVML's `getPowerUsage`.

To support NVIDIA's Multi-Instance GPU (MIG) architecture, Kepler first inspects whether MIG slices exist on a given device. If so, it iterates over each slice and retrieves per-process utilization data individually. Otherwise, it queries the full physical GPU. In both cases, the parent GPU ID is used as the key to unify resource attribution. For each PID returned by NVML, GPU utilization metrics are appended to the `ResourceUsage` field of the Kepler-internal `ProcessStats` structure. The following metrics are collected:

- **GPUComputeUtilization**: The percentage of compute engine usage (SM activity) over the sampling interval.
- **GPUMemUtilization**: The percentage of frame buffer memory usage per process.

Because NVML does not provide high-resolution energy counters, Kepler approximates GPU energy consumption by multiplying the instantaneous device-level power draw (`GetPowerUsage`) with the sampling interval duration (`SamplePeriodSec`). That is, energy per device is estimated as $\text{energy} = \text{power} (\text{mW}) \times \text{SamplePeriodSec}$. This coarse-grained sampling, typically performed every few seconds, limits the temporal resolution and may miss short-lived GPU activity.

If `GetProcessUtilization()` is not supported by the hardware or fails at runtime, Kepler falls back to using `GetComputeRunningProcesses()` combined with

per-process memory usage to estimate GPU utilization. In this mode, energy is attributed proportionally to memory usage rather than compute activity. Alternative backends such as Habana or DCGM are supported but do not offer per-process utilization data and are thus not used for fine-grained attribution in Kepler’s default configuration.

Summary of Inputs Tables 4.1 and 4.2 summarize the distinct types of input Kepler collects. Metric inputs provide raw resource and energy data, while metadata inputs allow this data to be mapped to containers, VMs, or system processes.

Metric Type	Source	Purpose
CPU hardware counters	<code>perf_event_open</code> via eBPF	Track cycles, instructions, cache misses per process
CPU software counters	Custom eBPF programs	Capture CPU time, IRQs, page cache activity
RAPL energy counters	<code>/sys/class/powercap</code>	Direct energy measurement for CPU and memory domains
Platform power	Redfish REST API, ACPI sysfs	Estimate total node energy from external sensors
GPU utilization	NVML (via Go bindings)	Track per-process compute and memory usage
GPU energy (approx.)	NVML power reading \times interval	Estimate per-device energy usage

TABLE 4.1: Metric inputs used by Kepler for energy and resource monitoring

Metadata Type	Source	Purpose
Container ID extraction	<code>/proc/<pid>/cgroup</code>	Identify container context of each process
Pod and namespace info	Kubelet API or Kubernetes API server	Map container ID to pod, namespace, container name
System process fallback	Internal constants + missing container ID	Label processes outside containers as <code>system_processes</code>
Kernel thread fallback	<code>cgroupID = 1</code>	Label root-cgroup processes as <code>kernel_processes</code>
Virtual machine ID	<code>machine-qemu-* .scope</code> + optional libvirt lookup	Label QEMU/KVM-based VMs by scope or libvirt metadata
GPU process association	PID-based matching via NVML	Associate GPU usage with Linux processes

TABLE 4.2: Metadata inputs used by Kepler to organize and label monitored workloads

Export Interface and Metric Exposure All metrics collected by Kepler are ultimately exposed via Prometheus after power attribution. This includes both raw utilization metrics (e.g. CPU time, instructions, cache misses) and derived energy metrics (e.g. power estimates per container). The Prometheus export format allows flexible time series queries and integration with Grafana or other observability platforms.

Estimator Sidecar and Model Inference In addition to its lightweight internal estimator, Kepler optionally supports an estimator sidecar container that uses more sophisticated regression models for power inference. The sidecar communicates with the exporter via a Unix domain socket and loads pre-trained models (e.g. Scikit-learn, XGBoost) suitable for online estimation in environments lacking direct power metrics. This mechanism is mainly intended for telemetry-sparse environments and is not used in the real-time deployment mode considered in this thesis.

Model Server and Model Training For environments where energy measurement is available (e.g. via RAPL or Redfish), Kepler provides a separate model server that facilitates training of machine learning-based energy models. This component ingests time-aligned Prometheus metrics and energy readings, applies preprocessing steps, and generates regression models that estimate power consumption based on utilization metrics. Both absolute and dynamic models can be trained, using different feature groups (e.g. time-based vs. instruction-based) and labeled according to power domain (e.g. core, package). The resulting models are stored in a hierarchical directory format and can be deployed in other environments via the estimator sidecar. The model server supports modular pipelines, allowing flexible input data sources, energy isolation techniques, and regression backends. This training loop is essential in contexts where hardware telemetry is available during development or profiling but not in production. While model training plays a key role in extending Kepler to new environments[121], it is not central to the goals of this thesis.

External Integration Kepler is designed to integrate seamlessly with existing observability tools. Prometheus is used to scrape metrics from the Kepler agent, and dashboards can be built using Grafana to visualize energy consumption across nodes, containers, or applications. While not required for core functionality, this integration facilitates operational awareness and debugging.

4.3.1.3 Attribution Model and Output

Kepler Configurability and Measurement Interval Kepler updates its input metrics at a configurable interval (default: `SamplePeriodSec` = 3 seconds), with the exception of Redfish-based measurements, which have a separate, user-defined interval (default: 15 seconds). Although utilization and RAPL energy metrics theoretically support more fine-grained sampling, Kepler performs attribution solely based on aggregated values within each configured sampling window. While this reduces system overhead, it may miss short-lived energy fluctuations. Kepler’s attribution framework is modular by design, allowing easy integration of new power sources through standardized interfaces. Depending on the availability of input metrics, Kepler uses either direct power readings or model-based estimation. In the absence of hardware telemetry (i.e., RAPL), Kepler can apply regression models trained on a reference system where accurate power readings are available. For this thesis, only scenarios where all relevant metrics are available (as discussed in § 4.3.1.2) are considered.

Division of Power into Idle and Dynamic Components Kepler conceptually divides total power consumption into *idle power* and *dynamic power*. Their sum constitutes the total (often named *absolute*) measured energy on both process and node levels. Dynamic power is correlated with resource utilization, while idle power represents the static baseline consumption that persists regardless of system activity.

This distinction is critical, as Kepler distributes these two components differently among processes [122]. Idle power attribution follows the Greenhouse Gas Protocol guidelines [123], which recommend splitting idle power across containers based on their size (i.e., resource requests relative to the total). Dynamic power, by contrast, is attributed proportionally to observed resource usage.

Node-Level Energy Attribution On the node level, Kepler directly uses RAPL energy readings from the `pkg`, `core`, `uncore`, and `dram` domains for all available sockets, reporting energy in millijoules. GPU energy is measured per device via NVML. Platform-level energy is retrieved via the configured source, typically Redfish. Kepler iterates through all exposed chassis members and internally converts Redfish power metrics (in watts) to milliwatts, which are then multiplied by `SamplePeriodSec` to produce energy values in millijoules. These can then be treated like standard metrics.

After collecting node-level energy metrics, Kepler updates the tracked *minimum idle power* if a new lower value is observed. The corresponding resource usage is also recorded. This tracking applies to all RAPL domains and GPU devices. Node-level dynamic energy is computed as the difference between total and idle energy. Additionally, Kepler calculates the residual category *Other* as platform power minus the sum of `pkg`, `dram`, and GPU power, separately for idle and dynamic metrics. This implicitly attributes all remaining energy to unspecified components (e.g. network interfaces, fans, or storage devices).

Process-Level Energy Attribution Process energy is attributed based on resource utilization metrics and node-level energy values. Using the most recent measurements of component, GPU (if enabled), and platform power, Kepler calculates each process's energy consumption. Idle energy is simply divided evenly among all processes. This is in contrast to Kepler's documentation, which states that idle energy should be divided by requested container size (in accordance with the GHG protocol [123]). Since container-level metadata is aggregated from per-process statistics, implementing size-based idle attribution at the process level is non-trivial. Nonetheless, this feature is advertised but not implemented, as noted by a `TODO` comment in the codebase.

Dynamic energy is attributed proportionally using the formula:

$$E_{process_{dyn}} = \left[E_{component_{dyn}} \cdot \frac{U_{process}}{U_{node}} \right] \quad (4.1)$$

where $U_{process}$ is the process's resource usage, and U_{node} is the total component resource usage indicated by RAPL. If no usage is recorded, energy is divided evenly among processes. The specific usage metrics used in the default ratio model are:

- **CPU**: based on `CPUInstructions` (fallback: `CPUTime`)
- **DRAM**: based on `CacheMisses` (fallback: `CPUTime`)
- **GPU**: based on `GPUComputeUtilization` (via NVML)
- **Other and Platform**: intended to use a configurable default metric

However, the default usage metric for `Uncore` and `Platform` domains is not set in the configuration, defaulting to an empty string. As a result, these metrics are not attributed based on usage and fall back to equal distribution. It is unclear whether this is a conscious design decision or an oversight.

The following formula 4.2 summarizes the complete energy attribution model used by Kepler at the process level. It combines all relevant energy domains: dynamic and idle energy across measured components (e.g. package, core, DRAM, uncore, GPU), as well as residual platform energy not accounted for by specific components. Each part of the equation reflects a distinct step in the attribution logic previously discussed, merging them into a single expression for total per-process energy consumption.

$$E_{\text{process}} = \sum_{\text{comp} \in \{\text{core, dram, uncore, gpu}\}} \left(\left[E_{\text{comp}}^{\text{dyn}} \cdot \frac{U_{\text{process, comp}}}{U_{\text{node, comp}}} \right] + \left[\frac{E_{\text{comp}}^{\text{idle}}}{N_{\text{processes}}} \right] \right) \\ + \left[\frac{E_{\text{platform}}^{\text{dyn}} - (E_{\text{pkg}}^{\text{dyn}} + E_{\text{dram}}^{\text{dyn}})}{N_{\text{processes}}} \right] + \left[\frac{E_{\text{platform}}^{\text{idle}} - (E_{\text{pkg}}^{\text{idle}} + E_{\text{dram}}^{\text{idle}})}{N_{\text{processes}}} \right] \quad (4.2)$$

4.3.1.4 Attribution Timing and Export Granularity

Kepler attributes energy at fixed internal intervals (default: 3 seconds). These deltas are exposed via Prometheus metrics such as `kepler_container_joules_total`, but the Prometheus scrape interval is user-defined and may not align with Kepler's update loop. If the export interval is not a multiple of the internal interval (e.g. 5s vs. 3s), metric misalignment can occur, leading to visible fluctuations even for stable workloads. Since Kepler does not smooth or interpolate values, this behavior is expected and intentional. For more stable time series, it is recommended to configure the export interval as a multiple of Kepler's internal interval.

This timing issue primarily affects metrics that are reported as cumulative deltas (e.g. energy in millijoules). For Redfish-based metrics, which are provided in watts and converted internally by Kepler into energy values by multiplying with the update interval, synchronization is less problematic. The conversion to energy is performed over a well-defined window, which inherently matches the Prometheus export interval, thus avoiding the same class of timing issues.

4.3.1.5 Validation and Research Context

Kepler has been adopted in various academic and industrial settings as a tool for estimating energy consumption at the container and pod level. In most cases, it is treated as a black-box exporter, with little investigation into the reliability or internal consistency of its reported metrics. While its integration with Kubernetes and Prometheus makes it convenient to use, its internal attribution mechanisms and modeling assumptions are rarely scrutinized in published work. Andringa[124] investigates Kepler, but lacks the necessary depth.

A notable exception is the study by Pijnacker et al. [50, 52], which constitutes the first dedicated empirical evaluation of Kepler's behavior and attribution accuracy.

Their work critically examines whether Kepler's per-container energy metrics correspond to expected utilization and measured system-level power under controlled conditions.

To this end, the authors design a testbed using a Dell PowerEdge R640 with dual Intel Xeon CPUs, operating a single-node Kubernetes cluster. Redfish/iDRAC power readings, validated using a wall power plug, are used as a high-confidence ground truth reference. Container CPU metrics and metadata are collected using Prometheus and cAdvisor. Kepler is deployed in version 0.7.2, configured to use RAPL for component-level power metrics and Redfish for platform-level readings.

The validation experiment employs a repeated CPU stress workload (`stress -ng -cpu 32`), combined with a set of idle containers left in the Completed state to test the attribution of idle power. Additional tests involve dynamic workload changes, including the deletion of idle pods during active load, to analyze Kepler's behavior during transitions in cluster state. These experiments reveal attribution inconsistencies across both idle and dynamic workloads.

Importantly, the authors isolate the source of Kepler's inaccuracy as its attribution logic, rather than its raw power estimation. While node-level energy estimates can match ground-truth readings closely, the logic used to assign portions of that energy to specific containers often fails to reflect actual utilization patterns. Inconsistent handling of kernel and system processes, as well as temporary spikes in attribution caused by metric timing mismatches, point to deeper architectural shortcomings. These and other limitations are summarized in the next subsection.

4.3.1.6 Limitations and Open Issues

The results of the evaluation by Pijnacker et al. reveal several systemic issues in Kepler's container-level energy attribution. In parallel, this thesis identifies additional design and implementation problems through source code analysis and direct experimentation.

Validation results from Pijnacker et al. [52]:

- **Incorrect idle power attribution:** Kepler assigns idle power equally to all containers, including pods in the Completed state. This leads to energy being attributed to containers that are no longer active, skewing total container-level metrics.
- **Latency mismatch artifacts:** A mismatch between fast-updating utilization metrics (e.g. CPU usage) and slower power metrics (e.g. Redfish at 60s intervals) causes transient attribution spikes. This effect is most pronounced during workload transitions.
- **Inconsistent attribution to system processes:** When idle containers are removed or when attribution is unclear, Kepler sometimes redirects energy consumption to generic "system processes", even when this does not match observed CPU activity. This fallback mechanism introduces further attribution noise.

- **Unstable behavior during dynamic cluster state changes:** In deletion experiments, the removal of idle pods triggered inconsistent redistribution of both idle and dynamic power, including unexplained reductions in power attributed to active workloads.
- **Observability gaps for Completed pods:** Once a pod transitions to the Completed state, it may no longer be visible to cAdvisor or other telemetry tools. This can lead to orphaned power assignments in Kepler, which continues to attribute energy to containers that are no longer observable.

Additional issues identified in this work While the attribution issues demonstrated by Pijnacker et al. are the most critical and empirically validated shortcomings of Kepler, a detailed inspection of the source code conducted as part of this thesis (see § 4.3.1.3) confirms these problems and reveals several additional implementation and documentation-related concerns. Although these issues are less severe in their impact, they further highlight the current limitations of Kepler as a mature and reliable observability tool.

- **Incomplete codebase:** Kepler’s source code contains over 1000 unresolved TODO markers, some located in critical modules such as the ratio-based power model. These incomplete sections may affect reliability or create hard-to-debug behavior in real deployments.
- **Discrepancy between documentation and implementation:** While Kepler’s documentation describes proportional idle power distribution based on container size or usage, the actual implementation uses equal distribution across all containers, regardless of their activity or footprint.
- **Outdated documentation and diagrams:** Both public-facing and internal documentation, including UML diagrams and developer notes, are out of date. This lack of alignment between the codebase and its documentation hinders reproducibility and extension.
- **Inadequate measurement intervals for heterogeneous workloads:** Although Kepler collects advanced eBPF-based metrics at high frequency, RAPL-based measurements are only sampled every three seconds. For workloads with heterogeneous container behavior or short-lived processes, this can drastically impact accuracy. Higher sampling intervals for RAPL-based data would allow more fine-grained attribution.

Despite these limitations, it is important to emphasize that **Kepler remains the most advanced and integrated open-source implementation for process-level energy monitoring in Kubernetes environments to date**. Its combination of kernel-level instrumentation, Prometheus integration, and extensible modeling capabilities makes it a uniquely valuable reference point and starting foundation for future research and tool development.

4.3.1.7 KubeWatt (Derived from Kepler)

As a direct response to the shortcomings identified in Kepler’s attribution model, Pijnacker developed *KubeWatt*, a proof-of-concept alternative designed for improved container-level energy observability in Kubernetes. While Kepler’s modular design

and eBPF-based telemetry collection provide flexibility, it suffers from attribution artifacts, particularly related to static power division, temporal misalignments, and system process handling. KubeWatt explicitly addresses these issues by adopting a simpler, more transparent approach centered around external power readings and CPU-based attribution.

Separation of Static and Dynamic Power A core improvement in KubeWatt is its strict separation between static and dynamic power. Unlike Kepler, which distributes idle power among all containers, including non-running ones, KubeWatt isolates static power entirely. Static power, including control plane activity and system overhead, is measured upfront using one of two initialization modes. It is then excluded from per-container attribution. Dynamic power is attributed solely to active containers based on their proportional CPU utilization. This separation eliminates attribution artifacts such as idle containers appearing to consume power.

Initialization Modes for Static Power Estimation KubeWatt introduces two initialization modes to measure or estimate static power: *base initialization* and *bootstrap initialization*. The base mode measures node power in an empty cluster to establish an accurate baseline, while the bootstrap mode estimates static power during active workloads by fitting a third-degree polynomial regression model to observed CPU and power values. The initialization result is stored and reused, based on the assumption that static power remains stable over time.

Simplified Attribution Model For container-level attribution, KubeWatt modifies the hierarchical power-mapping model originally proposed in [124]. It attributes dynamic node power to containers proportionally to their CPU usage, normalized over all active containers. (While the specific metric used for *CPU usage* is a central feature of Kepler, KubeWatt does address this specifically.) This avoids using the full node CPU metric, which includes kernel and system overhead already covered by static power. The attribution model is transparent, avoids container misclassification, and is robust against changes in container count.

Resilience Against Kepler's Pitfalls In contrast to Kepler, KubeWatt shows robustness under dynamic workload changes, such as container creation or deletion. It avoids misattributing power to terminated or inactive pods and mitigates power leakage into "system_processes" labels. Additionally, KubeWatt explicitly ignores control plane pods in the dynamic attribution, instead incorporating their idle load into the static baseline.

External Power Source Integration Unlike Kepler, which may rely on internal sensors or hybrid models, KubeWatt is built around a single, clearly defined power source: the Redfish API via iDRAC. Power data is abstracted via a modular interface, allowing extensibility to other external sources. This design choice avoids mixing sensor domains and contributes to more interpretable results.

Improved Evaluation Outcomes Empirical evaluation confirms that KubeWatt reduces RMSE in total node power estimation compared to Kepler, achieves accurate attribution even under stressor workloads, and avoids over-reporting container power. Notably, the estimator mode maintains high accuracy as long as container CPU utilization is stable and consistent with Prometheus scrape intervals.

Overall, KubeWatt represents a targeted refinement of Kepler's architectural and attribution approach, favoring interpretability and correctness over feature completeness. While limited in scope (e.g. no support for GPU or memory attribution), it successfully mitigates several of the critical limitations identified in Kepler.

4.3.1.8 Re-Release of Kepler Version 0.10.0

During the final stages of this work, Kepler version 0.10.0 was released as a significant architectural rewrite. While maintaining its fundamental role as a Prometheus exporter for container-level energy metrics, the new release introduces considerable changes to both its internal implementation and energy attribution methodology. This section provides an overview of the revised architecture and critically analyzes the implications of these changes in the context of container-level energy observability.

Implementation Changes Kepler v0.10.0 represents a ground-up redesign focusing on modularity, thread-safety, and accessibility. Mutex locks are used extensively throughout the codebase to ensure safe concurrent metric collection. Unlike previous versions, Kepler now requires only read-only access to `/proc` and `/sys` filesystems, eliminating the need for elevated privileges (`CAP_SYSADMIN`, `CAP_BPF`). This is marketed as a significant improvement in deployability and security.

Container detection still relies on traditional cgroup path analysis, with per-process cgroups parsed via regex matching to identify container runtimes and IDs. However, unlike prior versions, container-level resource metrics are no longer derived by aggregating per-process metrics. Instead, Kepler v0.10.0 treats containers as first-class workloads: CPU usage statistics for containers are read directly from cgroups, without requiring process-level aggregation.

Node-level CPU activity is determined via the Linux `/proc/stat` interface, using the formula:

$$\text{CPUActiveTime} = \text{TotalTime} - (\text{IdleTime} + \text{IOWaitTime}) \quad (4.3)$$

A node-level usage ratio is computed as:

$$\text{CPUUsageRatio} = \frac{\text{CPUActiveTime}}{\text{TotalTime}} \quad (4.4)$$

This represents a significantly simplified utilization model compared to prior versions, which relied on more granular hardware performance counters (e.g. instructions retired, cache misses). While the new architecture is once again designed in a modular way, this specific ratio model is not, perhaps suggesting that no user-selectable utilization metric is aimed for, as there was in the previous version.

At the power measurement layer, Kepler continues to rely on RAPL readings, now referred to as "energy zones". In addition to standard `package`, `core`, `uncore`, and `dram` zones, Kepler v0.10.0 dynamically detects the `psys` domain, expanding applicability to non-server-grade processors. Multi-socket systems are supported via automatic aggregation of identically named RAPL zones, with counter wraparounds

correctly handled through delta calculations based on maximum energy values.

Finally, pod lifecycle awareness has seen notable improvements. Kepler now tracks ephemeral and init containers explicitly, indexing container IDs via Kubernetes' native API server. This mitigates previous observability gaps for short-lived and Completed pods, which were previously problematic due to reliance on cAdvisor and cgroup detection alone.

Power Attribution Model The energy attribution model has undergone a substantial simplification. Kepler v0.10.0 attributes energy solely based on CPU time. The node's total RAPL-reported active energy is distributed proportionally to workload CPU activity:

- **Node-level attribution:** At each interval, total energy deltas are computed from RAPL readings. Active and idle energy components are calculated using the node's CPU usage ratio:

$$E_{\text{active}} = \Delta E \cdot \text{CPUUsageRatio} \quad (4.5)$$

$$E_{\text{idle}} = \Delta E - E_{\text{active}} \quad (4.6)$$

- **Process-, container-, and pod-level attribution:** Processes, containers, and pods are treated as independent workloads. Each receives a fraction of the node's active energy based on its CPU time share:

$$E_{\text{workload}} = E_{\text{node, active}} \cdot \frac{\text{CPUTimeDelta}_{\text{workload}}}{\text{CPUTimeDelta}_{\text{node}}} \quad (4.7)$$

It is important to emphasize that container metrics are no longer derived from per-process metrics. Instead, both processes and containers draw energy directly from node-level active energy based on their own independently tracked CPU usage statistics. This parallel accounting structure avoids process-level aggregation.

Critical Analysis While Kepler v0.10.0 improves accessibility, security, and operational simplicity, these enhancements come at the cost of reduced modeling fidelity. CPU time has replaced more nuanced metrics such as CPU instructions and cache misses for workload attribution. The new model assumes linear energy scaling with CPU activity, disregarding workload heterogeneity and hardware-level power behaviors such as frequency scaling or turbo boost. By not attributing idle power to workloads, Kepler focuses on actionable energy consumption linked to active resource use. While this limits full node-level energy accountability at workload granularity, it avoids inaccuracies introduced by arbitrary idle power distribution.

Additionally, Kepler's model assumes that CPU time directly correlates to power consumption, overlooking variations introduced by CPU frequency scaling, idle states, instruction-level differences, and workload-specific resource behaviors (e.g. memory-bound tasks). These factors can significantly distort power attribution, especially in heterogeneous or bursty workloads.

rom a research perspective, the simplification represents a methodological compromise: Kepler prioritizes operational deployability and stability over modeling granularity. While suitable for general monitoring, its current attribution model is less suited to detailed workload-specific energy analysis.

In the author's view, Kepler's redesign trades attribution accuracy for simplicity and usability. While this architectural shift benefits practical deployment, it diminishes the tool's value for research-focused energy observability. Finer-grained temporal attribution and more diverse utilization metrics would have been desirable developments.

4.3.2 Scaphandre

4.3.2.1 Overview and Goals

Scaphandre[125] is an energy monitoring agent designed to expose power consumption metrics at fine granularity, particularly in containerized and virtualized environments. Its name, derived from the French word for "diving suit", reflects its goal of providing deep insights into system-level energy consumption.

Scaphandre aims to attribute energy usage to individual processes, containers, or pods. It supports multiple deployment models: it can be installed directly on a physical host (where it can also monitor qemu/KVM-based virtual machines) or deployed in a container, measuring the energy usage of the host system, provided that the `/sys/class/powercap` and `/proc` directories are mounted as volumes. Most relevant to this thesis, Scaphandre can also be deployed on a Kubernetes cluster via a Helm chart, optionally alongside *Prometheus* and *Grafana*, allowing for convenient monitoring of Kubernetes nodes and containers.

4.3.2.2 Architecture and Metric Sources

Scaphandre is written in Rust and features a modular, extensible architecture built around two core components: *sensors* and *exporters*. Sensors gather energy-related data from the host system, while exporters format and expose this data to external systems. This design allows seamless integration into cloud-native observability stacks and automation pipelines.

Sensors Scaphandre's *Sensors* subsystem collects utilization and energy consumption metrics from the host system and makes them available to exporters. An abstraction layer, implemented in `sensors/mod.rs`, manages system topology (tracking sensors, CPU sockets, RAPL domains, and processes) and manages the generation of metric records.

The default Linux implementation, `PowercapRAPLSensor` (located in `powercap_rapl.rs`), constructs a power topology by reading Intel RAPL data from the `/sys/class/powercap` interface. By default, it identifies all available domains (and sockets) by matching directories with pattern `intel-rapl:<socket>:<domain>`, each containing a domain name and an `energy_uj` file reporting cumulative energy in microjoules. If no domain-level directories are found, Scaphandre triggers a fallback mechanism that omits subdomain detail and instead reads from the socket-level file, if available. This file represents the `package` (PKG) domain, which aggregates the energy consumption of the entire CPU socket. While PKG is a standalone

RAPL domain, it also serves as the root of the domain hierarchy. Notably, Scaphandre does not currently handle overflow in the `energy_uj` counter, a known limitation that has not yet been resolved despite user-reported inaccuracies [126].

In addition to the Powercap-based sensor, a Windows-only sensor is available that reads energy consumption directly from Intel or AMD-specific Model-Specific Registers (MSRs).

System utilization metrics are collected by helper functions implemented in `utils.rs`, which rely on Rust's `sysinfo` and `procfs` crates. These libraries extract data from virtual filesystems such as `/proc`, `/sys`, and `/dev`. When container support is enabled, cgroups are also read, but solely to map processes to containers. The collected metrics are stored in a custom data structure along with timestamps, while cgroup information is attached to each process as additional metadata labels. Apart from metrics of processes, CPU and memory, disk read/write operations are also collected.

The `sensors` abstraction layer also applies key data preprocessing steps, which are discussed in § 4.3.2.3.

Exporters Exporters are responsible for collecting metrics from sensors, storing them temporarily, and exporting them to external systems. Crucially, they also perform the attribution of energy and system metrics to specific scopes, which is discussed in detail in the following section. Similar to the sensor subsystem, Scaphandre uses an abstraction layer (implemented in `exporters/mod.rs`) to manage common exporter logic such as metric preparation and attribution. Individual exporters are implemented as pluggable modules. The `MetricGenerator` plays a central role by consolidating and attributing metrics across all scopes: the Scaphandre agent itself, the host, CPU sockets, RAPL domains, system-wide statistics, and individual processes.

The modular exporter architecture enables easy implementation of new output formats, and Scaphandre explicitly encourages developers to implement custom exporters if needed. Currently, exporters exist for *Prometheus*, *Stdout*, *JSON*, and *QEMU*, among others.

The *QEMU* exporter is particularly notable. It is designed for use on QEMU/KVM hypervisors and allows energy metrics to be exposed to virtual machines (VMs) in the same way that the `powercap` kernel module does on bare-metal systems. Specifically, the *QEMU* exporter writes VM-specific energy metrics to a virtual file system. Inside the VM, a second Scaphandre instance can read these files as if they were native energy interfaces. This mechanism mimics a bare-metal powercap environment, allowing software running in the VM to access energy data without direct access to RAPL or hardware sensors. This architecture is especially useful for breaking the opacity of power monitoring in virtualized environments, where such metrics are usually unavailable. If adopted by cloud providers, this could significantly improve visibility into energy consumption within public cloud VMs, supporting energy-aware software design even in virtualized infrastructures.

Measurement Interval Scaphandre's measurement interval is fixed at two seconds, as defined in the `show_metrics` function of the file `/exporters/prometheus`.

rs. This hardcoded interval determines how frequently the agent performs a new measurement by reading cumulative energy values from the RAPL interface. While RAPL counters are updated approximately every millisecond, Scaphandre does not take advantage of this high-resolution data. Reducing the interval could improve measurement accuracy and temporal granularity (especially for short-lived processes) but would also increase system overhead. As of now, modifying the interval would require changes to the source code.

4.3.2.3 Attribution Model

Scaphandre attributes power consumption to processes and containers using a proportional model based on CPU usage over time. At each sampling interval, it reads the system's total energy consumption from Intel RAPL counters and distributes this energy among all active processes according to their normalized CPU utilization.

The core of this attribution logic is based on CPU time as reported in `/proc`. For each process, Scaphandre accumulates CPU time in active states and excludes time spent in inactive states such as `idle`, `iowait`, `irq`, and `softirq`. This filtering is applied both at the per-process and system level, so that only time considered "active" is included in the normalization denominator. The result is a time-based utilization model that excludes idle-related CPU time from consideration.

Per-process energy is then computed using the following formula, conceptually implemented in `get_process_power_consumption_microwatts()`:

$$E_{\text{proc}}(t) = \frac{E_{\text{RAPL}}(t) \cdot \text{CPU}_{\text{proc}}(t)}{\sum_i \text{CPU}_i(t)} \quad (4.8)$$

where $E_{\text{RAPL}}(t)$ denotes the energy delta over the sampling interval t , and $\text{CPU}_{\text{proc}}(t)$ is the active CPU time of the process. The denominator includes the sum of active CPU time across all processes, excluding inactive states.

Container-level attribution is achieved by inspecting the cgroup path of each process and mapping it to a container or Kubernetes pod using runtime-specific metadata. When container context is available, Scaphandre enriches its per-process metrics with labels such as `container_id`, `kubernetes_pod_name`, and `namespace`. These metrics, such as `scaph_process_power_consumption_microwatts`, are then exposed via Prometheus and can be aggregated at container or pod level.

In addition to process- and container-level metrics, Scaphandre also reports host-level power consumption using the *PSYS* RAPL domains. These host metrics include total platform or package energy consumption, as available, and are exposed via metrics such as `scaph_host_power_microwatts` and `scaph_host_energy_microjoules`. Notably (as pointed out in § 2.4.2), the *PSYS* domain typically does not exist on server-grade systems, in which case Scaphandre adds the *PKG* and *DRAM*-packages to calculate host consumption. Unlike per-process energy values, these host-level metrics reflect total system energy use and are not adjusted to exclude idle CPU time.

Idle power consumption Scaphandre does not compute idle power directly, but it is possible to infer a residual estimate by comparing the total reported host power

to the sum of per-process power:

$$P_{\text{idle}} = P_{\text{Host}} - \sum P_{\text{proc}}$$

This difference may include contributions from idle power, system activity outside of user processes, or RAPL domain coverage gaps. However, this value is not part of Scaphandre's exported metrics and must be computed externally if needed.

This attribution methodology is used consistently across the Scaphandre exporters, including the Prometheus exporter. It forms the basis for container-aware energy attribution without requiring additional instrumentation or hardware performance counter support. Further discussion of this methodology's strengths, assumptions, and limitations follows in the next section.

4.3.2.4 Validation and Research Context

To date, no formal validation of Scaphandre's attribution methodology has been published. While the underlying RAPL interface used for energy measurement is widely accepted and validated in prior research, the specific proportional attribution model employed by Scaphandre has not been systematically evaluated against ground-truth data or instruction-based models. Despite this, Scaphandre has been used in academic and applied contexts for estimating the energy consumption of software systems. In most cases, it is treated as a black-box exporter of container-level energy metrics, with limited investigation into its internal measurement and attribution logic.

A more detailed assessment is presented by Tarara[109], who compares Scaphandre's reported per-process power consumption against both CPU utilization and instruction-based measurements. His case study reveals that Scaphandre tends to overestimate power consumption for lightweight processes under low-load conditions, due to its policy of distributing all observed energy among the small set of active processes. While the model excludes idle time from CPU usage calculations, it does not exclude idle power from total energy, leading to attribution artifacts. Tarara concludes that Scaphandre improves upon naïve utilization-based models but cannot match the precision of instruction-level approaches using tools such as `perf`.

4.3.2.5 Limitations and Open Issues

While Scaphandre offers a lightweight and transparent approach to energy attribution, several limitations emerge from its current implementation.

First, its fixed measurement interval of 2 seconds limits temporal resolution. Although the underlying RAPL interface supports much finer granularity, Scaphandre aggregates CPU activity over 2-second windows. During this time, the Linux scheduler may switch between dozens or hundreds of processes, depending on system activity. As a result, Scaphandre can only attribute energy based on average CPU utilization over the interval, potentially masking short-lived or bursty behavior.

Second, Scaphandre attempts to refine CPU-based attribution by subtracting inactive time (`idle`, `iowait`, `irq`, `softirq`) from the denominator of its proportional model. While this adjustment excludes clearly non-active states, it does not fully resolve the underlying ambiguity of CPU utilization as a proxy for energy. As noted by

Tarara[109], when overall system load is low, the total observed energy (especially idle platform power) is still fully distributed among a small set of active processes. This can result in inflated or misleading per-process energy values, particularly for lightweight workloads.

Scaphandre relies exclusively on Intel's RAPL interface for energy measurements. The developers of Scaphandre acknowledge the lack of detailed public documentation, especially for the PSys domain, which they assume to represent total SoC power. Their experiments also highlight ambiguity regarding domain overlaps (for instance, whether the DRAM domain is already included in PKG, or whether it must be treated as a separate component). These uncertainties may affect the interpretation of host-level energy metrics and the completeness of total system energy accounting.

In a comparison experiment between Scaphandre and other tools, Raffin[16] was unable to push Scaphandre's measurement frequency beyond 28 Hz, indicating a sub-optimal implementation. Despite being written in Rust, Scaphandre performed significantly worse than the Python-based tool *CodeCarbon*. Raffin measured Scaphandre's overhead at a non-negligible 3-4% at 10 Hz on an Intel server.

Finally, Scaphandre does not incorporate instruction-level or performance counter-based metrics. It cannot distinguish between processes with different execution intensities or memory behavior and assumes a uniform relationship between CPU time and energy use. This limits its ability to reflect differences in instruction throughput, stalling, or architectural efficiency across workloads.

4.3.3 SmartWatts

4.3.3.1 Overview and Goals

The PowerAPI implementation *SmartWatts*[54] is a software-defined, self-calibrating power 'formula' designed for estimating power consumption of containers, processes, and VMs. It aims to address the shortcomings of static power models by using online model adaptation (sequential learning) and runtime performance counters. Unlike many academic models that require manual calibration or architecture-specific training, SmartWatts adapts automatically to the host system and workload.

4.3.3.2 Architecture and Metric Sources

SmartWatts is written in Python. Understanding the architecture of SmartWatts and its differences from other energy monitoring tools is crucial. Using HWPC, RAPL, and CPU process metrics, SmartWatts collects performance data. At runtime, it uses power models based on cgroups and perf events alone to estimate, for each resource $\text{res} \in \{\text{CPU}, \text{DRAM}\}$, the host power consumption \hat{p}_{res} and the power consumption $\hat{p}_{\text{res}}(c)$ for all containers. SmartWatts uses \hat{p}_{res} to continuously assess the accuracy of the managed power models $M_{\text{res},f}$ to ensure that estimated power consumption does not diverge from the RAPL baseline measurement $p_{\text{res}}^{\text{rapl}}$. When the estimation diverges beyond a configurable threshold ϵ_{res} , SmartWatts triggers a new online calibration process for the model. When the machine is at rest (e.g. after a reboot), this method is also used to isolate the static energy consumption. A simple architecture can be seen in Figure 4.3.

In practical terms, SmartWatts implements a server-side powermeter (referred to as *power meter*) that consumes input samples and produces power estimations accordingly. The power meter is responsible for power modelling, power estimation, and model calibration. In addition, a client-side sensor (referred to as *sensor*) is deployed as a lightweight daemon on all cluster nodes. The sensor is responsible for static power isolation, event selection, cgroups, and event monitoring. This separation allows for heterogeneous cluster nodes.

FIGURE 4.3: SmartWatts Architecture

4.3.3.3 Attribution Model

As discussed in the previous subsection, the SmartWatts attribution model does not use RAPL metrics, opting only for process metrics. SmartWatts separates host energy consumption into static and dynamic power consumption:

$$p_{res}^{rapl} = p_{res}^{static} + p_{res}^{dynamic} \quad (4.9)$$

Static power is estimated by periodically logging RAPL package and DRAM power consumption. The *median* value and the *interquartilerange* (IRQ) are gathered from the measurements to define the static host power consumption as

$$p_{res}^{static} := median_{res} - 1.5 \cdot IRQ_{res} \quad (4.10)$$

This approach is meant to filter out RAPL outliers.

Dynamic power is estimated by correlating the CPU frequency f and the raw metrics reported by HWPC:

$$\exists f \in F, \hat{p}_{res}^{dyn} = M_{res}^f \cdot E_{res}^f \quad (4.11)$$

where E_{res}^f denotes all *events*. The model M_{res}^f is built from *elastic net* regression applied on the last k samples. To ensure that all container power consumptions are linear with regards to global power consumption, positive inference coefficients are enforced, and the intercept (or *bias term*) is constrained within the range $[0, TDP]$.

HWPC metrics are dynamically chosen based on the list of available events exposed by the host's *Performance Monitoring Units* (PMU), essentially creating a custom model based on available metrics. Not all available metrics are used, and statistical analysis (Pearson coefficient) is applied to determine worthy candidates.

Container power consumption is estimated by applying the inferred power model M_{res}^f at the scale of the container's events $E_{res}^f(c)$, as seen in formula 4.12. In formula 4.13, the intercept i is distributed proportionally to the dynamic part of the consumption of c .

$$\exists f \in F, \forall c \in C, \hat{p}_{res}^{dyn}(c) = M_{res}^f \cdot E_{res}^f(c) \quad (4.12)$$

$$\forall c \in C, \tilde{p}_{res}^{dyn}(c) = \hat{p}_{res}^{dyn}(c) - i \cdot \left(1 - \frac{\hat{p}_{res}^{dyn}(c) - i}{\hat{p}_{res}^{dyn} - i} \right) \quad (4.13)$$

In theory, one can expect $\hat{p}_{res}^{dyn} = p_{res}^{dyn}$ if the model perfectly estimates the dynamic power consumption, but in practice, an error $\epsilon_{res} = |p_{res}^{dyn} - \hat{p}_{res}^{dyn}|$ occurs. Therefore, container power consumption is capped at:

$$\forall c \in C, \lceil \tilde{p}_{res}^{dyn}(c) \rceil = \frac{p_{res}^{dyn} \cdot \tilde{p}_{res}^{dyn}(c)}{\hat{p}_{res}^{dyn}} \quad (4.14)$$

This approach also allows calculating a confidence interval of the power consumption of containers by scaling down the observed global error:

$$\forall c \in C, \epsilon_{res}(c) = \frac{\tilde{p}_{res}^{dyn}(c)}{\hat{p}_{res}^{dyn}} \cdot \epsilon_{res} \quad (4.15)$$

In order to improve estimation accuracy, the following configurable parameters are used:

- CPU TDP in Watt (default: 125)
- CPU base clock in MHz (default: 100)
- CPU base frequency in MHz (default: 2100)
- CPU and DRAM error threshold in Watt (default: 2)
- Minimum number of samples required before attempting to learn a power model (default: 10)
- Size of the history window used to retain samples (default: 60)
- Measurement frequency in milliseconds (default: 1000)

4.3.3.4 Validation and Research Context

With RAPL being used as ground truth for dynamic power estimation model re-calibration, it is important to note that the SmartWatts validation focuses on model accuracy when compared to RAPL values, rather than values obtained from an external source of power data. The SmartWatts validation evaluated the quality of power estimation under sequential and parallel workloads, the accuracy and stability of power models, and the overhead of the *sensor* component. Standard benchmarks like Stress-NG and NAS Parallel Benchmarks were used.

While no advanced statistical analysis was conducted, the validation shows that, for an error threshold of 5 Watts for CPU and 1 Watt for DRAM, power consumption can be reliably estimated with errors below 3 Watts and 0.5 Watts, respectively. The only case where the error exceeds the threshold is at the CPU idle frequency. Model stability is shown to improve significantly when lower recalibration frequencies are used. SmartWatts successfully reuses a given power model for up to 594 estimations, depending on frequency. Monitoring overhead is observed to be 0.333 Watts for the PKG domain and 0.030 Watts for the DRAM domain on average, at a measurement frequency of 2 Hz. The authors consider this overhead negligible.

4.3.3.5 Limitations and Open Issues

SmartWatts offers a compelling solution for dynamic, container-level power estimation through self-calibrating models based on performance counters. However, its applicability remains domain-specific. The central assumption is that RAPL, while accurate, is too coarse-grained for attributing power to individual containers or processes. This premise is debatable: RAPL offers low-overhead, high-frequency measurements and may be sufficient for many use cases, particularly in homogeneous or single-tenant systems. Whether SmartWatts' added complexity is justified depends on how fine-grained the attribution needs to be.

SmartWatts excels when more granular telemetry (e.g. perf events) is available and container-level attribution is critical. Yet its current implementation models only CPU and DRAM domains, limiting its ability to provide a comprehensive energy profile.

The design allows operators to supply hardware-specific values (e.g. CPU TDP), while falling back to sensible defaults. This improves usability without sacrificing model accuracy.

Finally, while SmartWatts' runtime calibration and dynamic event selection enhance adaptability, they introduce complexity. The event selection mechanism relies on statistical heuristics, which may not generalize well across systems. Moreover, under highly dynamic conditions, frequent recalibrations may affect stability.

In summary, SmartWatts is well-suited for environments requiring high-resolution attribution beyond RAPL's capabilities, but its scope, complexity, and assumptions warrant careful consideration depending on the target use case.

Chapter 5

Conclusion and Future Work

5.1 Summary of Findings

This thesis confirms that attributing energy consumption to containerized workloads remains an inherently complex and uncertain task. While existing tools can provide detailed measurements, none can achieve exact results: fundamentally, every method introduces estimation errors due to limitations in data sources and methodological assumptions. Measurement uncertainty is unavoidable and varies depending on the chosen metrics and approach.

The analyzed tools demonstrate significantly different design philosophies, largely reflecting their intended audiences and operational environments. For example, Kepler's earlier versions (v0.9.0) prioritized measurement granularity and resource-level accuracy, relying on eBPF instrumentation and hardware counters to achieve fine-grained attribution. In contrast, Kepler's latest version (v0.10.0) adopts a simplified, CPU-time-based attribution model that sacrifices accuracy in favor of deployability, security, and operational stability, suggesting a strategic shift.

The intended audience of a measurement tool is a critical factor influencing its architecture. Researchers and infrastructure engineers working on system optimization may demand maximal granularity and accuracy, accepting additional overhead and complexity. Developers, in contrast, often seek only high-level visibility into container-level energy consumption and may prefer black-box tools that abstract away implementation details. Cluster operators balance energy awareness with priorities such as security, availability, and maintainability; conditions that typically preclude privileged monitoring techniques like eBPF.

Across all tools, Intel's RAPL interface emerges as the most reliable and promising source of real-time energy telemetry for CPU and DRAM domains. Its millisecond-level update frequency theoretically enables highly granular measurements. However, most tools (including Kepler) fail to exploit this potential. Multi-second sampling intervals remain standard, reducing the fidelity of captured workload dynamics and limiting attribution accuracy, especially for heterogeneous workloads characterized by short-lived or bursty processes. Granular temporal analysis is thus identified as a key requirement for accurate energy attribution in complex environments. Fine-grained tracking better captures workload diversity and transient behavior but introduces computational overhead. Tools attempt to balance these competing concerns, but no clear consensus or universally optimal strategy emerges.

Another important trade-off lies between estimation and accuracy. While perfect energy attribution is unattainable, approximate models provide valuable insights even at lower precision. This thesis argues that estimation remains worthwhile, especially in multi-tenant and dynamic environments where detailed hardware telemetry is unavailable or incomplete.

Notably, all examined tools focus exclusively on CPU, RAM, and GPU energy consumption. No attempt is made to estimate power consumption of other system components such as storage devices or network interfaces. Extending measurement capabilities beyond the core compute elements presents a significant research opportunity. While such estimations are inherently less precise, even approximate visibility could enhance observability and inform optimization efforts.

In conclusion, energy attribution in containerized systems is a balancing act between detail and practicality. Existing tools demonstrate that both high-accuracy and operational simplicity are valid design goals, serving different user groups and system environments. RAPL remains central to accurate measurement, but practical deployment constraints often limit its effective use. Achieving reliable and actionable power monitoring requires careful architectural decisions, guided by the specific needs of the intended audience and the realities of the deployment environment.

5.2 Critical Reflection

5.2.1 Methodological Reflection

This thesis adopts a purely analytical approach, centered on literature review, code analysis, and architectural evaluation of existing container-level energy attribution tools, as well as potential sources of information. This methodological choice aligns with the intended scope of the project: as a VT2-level research work, the thesis was designed to provide a theoretical foundation for subsequent practical development.

While the thesis proposes concrete recommendations for future tool design (see § 5.3), it deliberately refrains from developing a full tool architecture or implementation. Instead, the findings are intended to inform such efforts in future research, particularly within the scope of the author's upcoming master's thesis.

While empirical validation through experimental benchmarking was deliberately omitted to prioritize tool coverage and architectural analysis, this remains a methodological limitation. Validation insights from existing literature were integrated where available.

The focus on Linux and Kubernetes environments further narrows the applicability of the findings. Alternative infrastructures, proprietary tools or telemetry sources (e.g. OEM-specific BMC energy reporting interfaces) were not explored in depth. This reflects both the author's area of expertise and the practical relevance of Kubernetes in modern cloud environments but limits generalizability.

Despite these limitations, the thesis's core strengths lie in its detailed inspection of source metrics, tool architectures and source code, combined with a practical understanding of Kubernetes-based deployments. This approach allowed the identification of undocumented behaviors, implementation inconsistencies, and unaddressed design trade-offs in tools such as Kepler, Scaphandre, and SmartWatts.

In summary, while empirical validation and cross-environment generalization are lacking, the thesis successfully fulfills its role as a theoretical exploration of container energy attribution, providing a solid analytical foundation for future tool development and evaluation.

5.2.2 Tool Adoption in Real-World Systems

A critical reflection of container-level energy attribution tools reveals significant barriers to their adoption in production environments. Chief among these are security concerns and the need for privileged access. Tools that rely on kernel-level instrumentation, such as eBPF or `perf_event_open`, often require elevated permissions, introducing potential security risks. For most cluster operators, energy monitoring remains a secondary concern compared to reliability, availability, and security. This limits the practical deployment of high-precision tools in real-world systems.

Operational simplicity frequently outweighs measurement accuracy. Tools with complex configurations, hardware-specific dependencies, or non-standard export interfaces are typically avoided, even if they promise higher measurement fidelity. In practice, both industry users and academic researchers often treat energy monitoring tools as black boxes. This is evident from the widespread use of tools like Kepler and Scaphandre without detailed validation or configuration tuning. While these tools offer configurability, leveraging it requires substantial technical understanding, which many users lack or are unwilling to invest.

As a result, most energy monitoring tools prioritize usability over accuracy. Prometheus integration, simple deployment (e.g. via Helm charts), and minimal security concerns are often deemed more important than methodological rigor. No tool analyzed in this thesis explicitly targets researchers seeking maximal measurement accuracy; instead, tools implicitly address operators who require straightforward observability solutions.

Finally, tool design often fails to recognize the fundamentally different needs of developers, operators, and researchers. Currently, no single tool effectively caters to all these audiences. This segmentation of user requirements, combined with practical deployment constraints, helps explain why most existing tools settle for operational simplicity at the expense of measurement accuracy.

5.2.3 Transparency, Trust, and Black-Box Measurement

A fundamental challenge in container-level energy attribution is the reliance on inherently opaque measurement interfaces. Critical telemetry sources such as Intel RAPL, NVIDIA NVML, and platform-level BMC sensors provide essential power and energy data, yet their internal operation and measurement scopes remain poorly documented. For instance, both Scaphandre and Kepler developers acknowledge uncertainty regarding the exact coverage of RAPL domains, most notably PKG and PSys. This lack of clarity complicates both tool implementation and the interpretation of reported energy metrics.

Black-box measurement interfaces hinder the development of accurate and explainable energy monitoring tools. When the underlying telemetry mechanisms are closed, tool developers are forced to make assumptions which propagate into the attribution models and directly impact reported results. Without visibility into how energy

counters are computed or which hardware components are included, users cannot fully trust the reported energy consumption data, nor can they debug unexpected results.

To address this, future energy monitoring frameworks should:

- Clearly document all assumptions related to telemetry sources and attribution models.
- Provide visibility into the source and scope of every reported metric.
- Encourage open standards for energy telemetry, advocating for greater transparency in RAPL, NVML, and similar interfaces.

5.2.4 Energy Attribution Philosophies

The analysis confirms that energy attribution models (container-centric, shared-cost, and residual modeling) reflect fundamentally different perspectives. What is considered a "fair" distribution depends on the user's priorities: developers, operators, or researchers will each favor different approaches.

Current tools often make implicit attribution decisions, especially regarding idle power and system processes, without clear documentation. This obscures how reported metrics should be interpreted.

To improve transparency and usability, future tools should:

- Clearly document their attribution model.
- Where feasible, allow users to choose between attribution strategies.
- Make residual power explicit rather than hidden in shared costs.

5.3 Recommendations for Future Tool Development

5.3.1 Towards Maximum-Accuracy Measurement Tools

Future container-level monitoring tools should prioritize temporal resolution, metric flexibility, and modular attribution models to maximize measurement accuracy. Based on the findings of this thesis, the following design principles are recommended:

High-Resolution Hardware Metrics RAPL-based measurements should support sub-second sampling intervals configurable by the user. Intervals as low as 50 milliseconds (close to RAPL's practical resolution limit) would enable significantly finer-grained power attribution, especially in heterogeneous or bursty workloads. Critically, power readings should be attributed directly upon collection, avoiding fixed aggregation cycles that dilute temporal precision and introduce attribution inaccuracies.

Decoupled Metric Handling Metric collection loops should differentiate between high-frequency (e.g. RAPL, eBPF) and low-frequency (e.g. Redfish, IPMI) sources.

Separating high-priority, high-frequency metrics from slower telemetry sources minimizes performance overhead and maximizes the utility of each metric type.

Multi-Metric Integration Tools should support combining diverse telemetry sources, such as RAPL, Redfish, ACPI, and BMC, in a coherent manner. Coarse-grained metrics (e.g. Redfish node-level power) can be fused with fine-grained metrics (e.g. RAPL domain-level power) to interpolate or validate measurements. However, care must be taken to preserve the distinction between direct measurements and model-based estimations when combining such sources.

User-Configurable Estimation Modules Modular estimation frameworks should be employed for subsystems lacking direct telemetry, such as storage devices or network interfaces. Default models can provide reasonable estimates based on automatic device detection (e.g. storage device type, or link speed for network interfaces). However, advanced users should be able to override idle, maximum, and typical power values to refine model accuracy.

Selectable or configurable Attribution Models Energy attribution should support multiple modeling approaches, ideally selectable at runtime. Examples include container-centric models, shared-cost models, or hybrid methods. Importantly, idle and system-level energy consumption should be accounted for explicitly, not implicitly merged into container totals, improving transparency and accuracy.

Self-Calibration Support Tools should offer automated or semi-automated calibration methods, such as idle power calibration or workload-based calibration inspired by Kavanagh et al. [12]. Where possible, standardized interfaces for integrating external measurement devices should be considered, enabling users to validate or refine energy models via external power meters.

Standards-Based Implementation Wherever feasible, tools should adhere to standardized system interfaces such as the Linux `powercap` framework for RAPL access, avoiding proprietary solutions. This facilitates long-term maintainability and eases deployment across heterogeneous environments.

In summary, a high-accuracy monitoring tool must prioritize both technical rigor and architectural flexibility. Drawing from design strengths observed in Kepler, KubeWatt, Scaphandre, and SmartWatts, future tools should offer high-resolution measurements, modular estimation, and transparent energy attribution as core design objectives.

5.3.2 Addressing Missing Domains: Disk, Network, and Others

No current container-level energy monitoring tool provides direct measurements or estimations for storage devices or network interfaces. Nevertheless, for a comprehensive understanding of node-level energy consumption, these components should not be neglected.

Modular Estimation Frameworks Future tools should include optional, modular estimation models for disks and network interface controllers (NICs). Such models could leverage existing system metrics such as I/O request counts, throughput

rates, or link speeds as input signals. For example, storage energy estimation could differentiate between SSDs and HDDs based on device identification, using I/O operations as a proxy for activity levels. Similarly, NIC models could base estimations on transmitted and received data volumes or link activity states.

Inherent Accuracy Limitations These estimations will inevitably remain less accurate than direct telemetry from hardware sensors. However, including such models can enhance the completeness of node-level energy consumption analysis, particularly in environments where disks and NICs constitute non-trivial portions of total power draw.

Residual Energy Utilization In cases where total node power is known (e.g. via Redfish or BMC sensors) and major contributors like CPU and memory are directly measured, residual energy (the unaccounted portion) could be partially attributed to storage and networking components. However, reliance on residual energy must be approached cautiously, as it risks compounding measurement and attribution errors.

Configurability Estimation models should remain user-configurable. While default values enable ease of use for casual users, advanced users should be able to fine-tune idle power, maximum power, and activity-to-power correlation parameters to improve estimation accuracy.

In summary, although disk and network power estimations are inherently imprecise, including them in a modular and configurable manner would significantly enhance the practical value of container-level energy monitoring tools.

5.3.3 Balancing Accuracy and Overhead

The pursuit of maximum measurement accuracy inevitably increases monitoring overhead. Future tools should address this trade-off by offering distinct operational modes, allowing users to select between accuracy and resource efficiency based on their specific needs.

'Precision' Mode In this mode, all available telemetry sources and fine-grained attribution models should be enabled. High-frequency sampling intervals, detailed container-level breakdowns, and optional estimations for secondary components (e.g. disks, NICs) provide maximal measurement detail. This mode is intended for research, validation, or auditing scenarios where energy transparency is prioritized over runtime performance.

'Lightweight' Mode Conversely, a lightweight mode should disable high-frequency probes, omit low-relevance subsystems, and focus on core power consumers such as CPU and memory. Sampling intervals can be relaxed, and coarse-grained metrics prioritized. This configuration is suitable for production environments where minimizing monitoring overhead is critical.

Mode Selection Not all environments or users require maximum accuracy. By providing predefined operational modes, tools can adapt to a wide range of use cases

without forcing users to manually configure every parameter. However, manual overrides should remain possible for expert users seeking fine control.

In summary, supporting both ‘precision’ and ‘lightweight’ modes allows monitoring tools to serve diverse operational contexts without compromising on flexibility or usability.

5.3.4 Supporting Multiple User Roles and Needs

Container-level energy monitoring tools must accommodate a diverse range of users, each with distinct goals and expectations. A future-proof tool should address these needs through architectural modularity, clear defaults, and extensive documentation.

Developers Developers typically seek simple, per-container energy consumption totals to guide software optimization. Their focus is on understanding the energy impact of specific applications or containers, without concern for the idle power waste or baseline energy consumption of the broader system. Minimal setup complexity and straightforward metric outputs are priorities for this user group.

Operators Infrastructure operators require system-wide energy observability, not limited to individual containers. Their goals include identifying idle energy waste, optimizing resource utilization, and avoiding performance degradation due to throttling or resource contention. Operators value transparency, stability, and actionable insights across the entire infrastructure stack.

Researchers Researchers demand the highest levels of accuracy, configurability, and architectural transparency. They require detailed documentation of attribution models, known limitations, and telemetry sources, alongside access to raw metrics and calibration options. Flexibility and reproducibility are critical requirements for this audience.

Serving All Audiences To accommodate these varied needs, monitoring tools should adopt a modular architecture with:

- Sensible, production-ready defaults for black-box usability.
- Optional advanced configuration layers for expert users.
- Clear and comprehensive documentation describing methods, assumptions, and limitations.

Recognizing that many users will treat the tool as a black box, default configurations must produce reasonable, usable results without requiring manual tuning. However, advanced users should retain the ability to inspect, customize, and extend the tool’s behavior.

In summary, serving developers, operators, and researchers simultaneously requires balancing simplicity, flexibility, and transparency within the tool’s design.

5.3.5 Energy Metrics for Virtualized Environments

Energy attribution within virtualized environments, particularly for Kubernetes clusters running inside virtual machines (VMs), remains a challenge. Existing monitoring tools primarily target bare-metal deployments, leaving a significant gap in energy observability for cloud-based and virtualized infrastructures.

Existing Approaches Two conceptual approaches have been explored:

- **Scaphandre’s QEMU Passthrough:** Implements a basic export mechanism by writing host-side energy metrics to a virtual file system accessible by guest VMs running an identical instance of Scaphandre. This approach is functional but limited, since input and output metrics must correlate to serve identical instances.
- **Kepler’s Hypercall Concept:** Proposes using hypercalls as a mechanism for host-to-guest metric transfer. However, this concept remains unimplemented.

Future Directions Future monitoring tools should prioritize the development of standardized telemetry export mechanisms to enable accurate energy monitoring within VMs. Potential approaches include:

- Hypervisor-supported hypercalls specifically designed for energy metrics.
- Virtio-based APIs to expose host-side telemetry directly to guest VMs.
- Enhanced QEMU or container runtime interfaces capable of exporting power data.

Relevance Given the prevalence of virtualized infrastructure in modern cloud environments, particularly for managed Kubernetes platforms, solving this problem would significantly broaden the applicability and adoption of energy observability solutions.

In summary, enabling reliable host-to-VM energy metrics passthrough represents a critical development priority for future container-level energy monitoring tools.

5.3.6 Standardization and Hardware Vendor Transparency

Measurement accuracy in container-level energy monitoring is fundamentally limited by the availability and transparency of hardware telemetry. Addressing these constraints requires both industry-wide standardization efforts and increased openness from hardware vendors.

Hardware Vendor Responsibility Vendors should provide native power telemetry for additional system components, such as network interface cards (NICs), storage devices, and peripheral subsystems. These metrics should be accessible via standardized, open interfaces to facilitate direct measurement and reduce reliance on model-based estimations.

Expanding Telemetry Standards Existing interfaces like Redfish, which currently expose node-level power data, could be extended to include per-component power

reporting. Similarly, the adoption of open, vendor-neutral standards for exposing telemetry at the subsystem level would significantly enhance energy observability.

RAPL Transparency The lack of public documentation regarding Intel's Running Average Power Limit (RAPL) interface remains a barrier to fully understanding and validating the reported power domains. Vendors should disclose the internal structure and calculation methods of such telemetry systems to resolve current 'black-box' concerns identified by tool developers, including Kepler and Scaphandre contributors.

In summary, improving measurement precision at the workload level depends not only on software design but also on cooperation from hardware manufacturers and industry standards bodies. Transparent and standardized telemetry interfaces represent a critical enabler for future progress in energy observability.

5.4 Broader Research and Industry Opportunities

The advancement of energy observability in containerized environments extends beyond tool development. Broader collaboration across industry stakeholders and research communities is essential to drive progress.

Role of Standards Organizations Organizations such as the Cloud Native Computing Foundation (CNCF) and Kubernetes Special Interest Groups (SIGs) could play a central role in promoting standard APIs for energy metric collection and dissemination within cloud-native environments. Establishing best practices and reference implementations would encourage adoption and consistency across tools.

Hardware Manufacturer Involvement Hardware vendors are positioned to directly influence the quality and availability of energy telemetry data. By exposing accurate and accessible power metrics across all major system components, manufacturers can enable precise energy measurement without reliance on coarse or estimated models. Collaboration with open-source communities could further support development of vendor-agnostic solutions.

Sustainable Cloud Computing Energy observability should be recognized as a foundational component of sustainable cloud computing. Accurate energy measurement at the workload level enables informed optimization decisions, supports regulatory compliance, and advances corporate sustainability goals. As such, energy transparency should be integrated into both research agendas and industry roadmaps for cloud infrastructure development.

In summary, advancing energy observability requires coordinated efforts spanning tool developers, standards bodies, hardware vendors, and sustainability-focused initiatives.

5.5 Closing Remarks

Energy consumption measurement at the container or workload level remains a complex and evolving challenge. This thesis has identified key architectural and

methodological features that future monitoring tools should incorporate to enhance measurement accuracy, architectural flexibility, and practical usability.

However, progress in this field is constrained not only by technical trade-offs (such as balancing accuracy against monitoring overhead) but also by external limitations. Chief among these are the lack of transparent hardware telemetry, incomplete standardization of power reporting interfaces, and the absence of established methodologies for energy attribution in virtualized environments.

The recommendations presented in this chapter are intended to guide both tool developers and researchers. By integrating high-resolution hardware metrics, modular estimation frameworks, user-configurable attribution models, and standardized interfaces, future tools can advance the state of energy observability in containerized infrastructures.

Ultimately, energy-aware computing practices will become increasingly relevant as the industry shifts towards sustainable cloud operations. Improved energy transparency at workload granularity represents a critical foundation for enabling these efforts.
